"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, NOVEMBER 2, 1911.

ARISTOTLE AS BIOLOGIST.

The Works of Aristotle, Translated into English. De Generatione Animalium. By Prof. A. Platt. Price 7*s.* 6*d.* net. De Partibus Animalium. By Dr. W. Ogle. Price 5*s.* net. Vol. iv., Historia Animalium. By Prof. D'Arcy W. Thompson. Price 10*s.* 6*d.* net. (Oxford: Clarendon Press, 1910–11.)

THE biological treatises of Aristotle are one of the chief marvels of antiquity. Remarkable in themselves for the evidence they give of the extraordinary powers of observation and reasoning possessed by their industrious author, they become truly astonishing when considered as only a comparatively small part of the life-work of a philosopher who entered profoundly into every department of human knowledge. The view has sometimes been entertained that after all Aristotle in his physical treatises was a mere copyist, that these works are rather of the nature of a literary compilation from sources now mainly lost than a record of original research and observation. A moderately careful study of, say, the "History of Animals" is sufficient to show that this is an error. Aristotle had undoubtedly made himself acquainted with what we should now call the "literature of the subject," and when it seems necessary he quotes from earlier writers. But it is not his way to borrow their statements uncritically. If Herodotus or Ctesias makes what he considers to be a mistake, he does not hesitate to say so. Moreover, the "History" teems with what are beyond all reasonable doubt good first-hand observations derived from actual dissection.

That errors should be numerous is only what might be expected considering the necessary limitations to research in the fourth century B.C. But it must be allowed that in his zoological and physiological speculations Aristotle displays reasoning powers of the highest order, and indeed it is often difficult to see that with the only data open to him he could have come to any sounder conclusions. It is curious that in the case of the strange phenomenon of hectocotylisation in the dibranchiate cephalopoda the Greek fishermen were right and Aristotle was wrong. But even here, as Prof. Platt remarks, he seems justified on the evidence before him. He could see no connection of the hectocotylised arm with the vasa deferentia, and "it is no wonder that he thought this decisive against the theory of the fishermen. He only deserves credit for doing so."

But in spite of this and many other errors perhaps equally excusable, it is undeniable that the three treatises before us contain an immense amount of accurate observation and skilful reasoning. Speaking of the "De Generatione Animalium," Prof. Platt says with truth, "should any man of science come fresh to the reading of this treatise, he will, I think, be amazed and delighted to see what grasp and insight Aristotle displays in handling questions which still absorb us after all the time" that has since elapsed.

The question of the dates of the composition of these books is of considerable interest in its bearing on Aristotle's more strictly philosophical work. Prof. D'Arcy Thompson lays stress on the frequency of reference in the "History of Animals" and other Aristotelian writings to the island of Lesbos and places near it. From this and other evidence he inclines to the view that Aristotle's natural history studies were carried on, or mainly carried on, between his two periods of residence in Athens, for during this interval he is known to have lived for two years in Mitylene, before his summons to the Court of Philip to undertake the tutorship of Alexander. Mr. Warde Fowler, on the other hand, thinks it probable that the "History" was at any rate begun in early life, the foundations being no doubt laid during his boyhood at Stageirus.

"This little town," as Mr. Fowler points out, "is placed in a most favourable position for a naturalist. It lies on a sea abounding in fish; above it rise the wooded heights of the eastern coast of the Chalcidic peninsula on which it stands; only a few miles distant is the river Strymon, which was so famous for water- and marsh-loving birds, as to give its name as a perpetual epithet to at least one species ['Strymoniæ grues']. Straight across the sea from Egypt and the Soudan came, and still come, every spring, multitudinous armies of migrating birds; they rest awhile about these rivers of the Thracian coast,

and then pursue their way northwards, crossing the Balkan Mountains into the plains of the Danube and Russia, to return again in the autumn. And, of course, for an inquiring naturalist a seaport town is always a desirable place, for here come sailors from foreign lands with tales of strange birds and beasts and plants, specimens of which they sometimes bring home with them. . . . We may be sure that young Aristotle was quick to profit by these chances."

Whatever may have been the point in Aristotle's career at which the "History" was projected, there can be little doubt that he was always taking such opportunities as offered for making additions and corrections. It is also reasonable to suppose that the book as we have it may contain annotations by some of his pupils. The treatises "De Partibus" and "De Generatione" are shown by internal evidence to be later as a whole than the "History."

The present excellent translations will serve, it may be hoped, to induce many students of the history of biological knowledge to undertake an examination at first hand of the works of this great scientific pioneer. Aristotle suffers little by intelligent translation, for his excellence lies in the matter of his writings rather than in their form. "The author himself," as Prof. Platt justly observes, "would have been the last man in the world to complain of any sacrifice of graces of style." Though the translators have no doubt nearly always succeeded in "representing as exactly as possible what Aristotle said or meant to say," it must not be supposed that they have denied themselves the use of good and vigorous English. Dr. Ogle's translation of the "De Partibus" in especial (a revision of his former well-known version) is admirable as a piece of literary workmanship. The notes of all three translators are good and useful so far as they go; but to produce a completely annotated edition of Aristotle's biological works in the light of modern knowledge would be a task from which the boldest might shrink. The typography and general get-up of these volumes are all that could be desired, and are worthy of the reputation of the Clarendon Press. It should always be remembered with gratitude that their publication is due to the generous provisions of the will of the late Prof. Jowett. F. A. D.

SOUTH AFRICAN ORCHIDS.

Icones Orchidearum Austro-Africanarum Extra-Tropicarum; or, Figures, with Descriptions of Extra-Tropical South African Orchids. By Dr. Harry Bolus. Vol. ii., pp. vi+200+100 plates. (London: Wm. Wesley and Son, 1911.) Price 2*l.* 2*s.* net.

TO Dr. Bolus's many botanical friends this volume, his last contribution to South African orchidology, has a special interest. Its production was the ostensible motive of his frequent journeys home during the past few years, and the revision for the press of its last few pages was completed on the eve of his death, which occurred shortly after his arrival in England early in the summer of the present year. The copies of his book, distributed by his niece and co-worker, Miss H. M. L. Kensit, are a fitting memento of the author and of the important influence he exerted on the progress of botanical exploration in South Africa. Bolus's botanical work was not confined to the study of the orchids. His wide and critical knowledge of the heaths is embodied in his contribution on that family in the "Flora Capensis"; and his extensive herbarium, which now passes to the South African College, bears witness to his general knowledge of the flora. But he will probably be best known for his careful study of the orchids, the results of which are embodied in various papers, but especially in the volume on the "Orchids of the Cape Peninsula" and the two volumes of the "Orchids of South Africa," the second of which is the subject of this notice.

The plan of the book is uniform with that of vol. i., which appeared in two parts (1893 and 1896 respectively). Excepting a few double plates and one on which are figured two species of Mystacidium discovered by, and dedicated to, Miss Alice Pegler, of Kentani, each of the hundred plates is devoted to one species; and the text consists of a corresponding number of quite separate technical descriptions. A characteristic feature is the duplication of each description in Latin and English. The distribution of each species is indicated by a citation of localities with collectors' names and numbers, and an indication is given of the source or sources from which the actual specimens figured were derived. The great majority of the plates were drawn from living specimens by Dr. Bolus himself, and the noting on the plate of the exact date at which the drawing was made shows that the material for the volume had been accumulating for more than twenty years. The extended period of preparation accounts for a slight want of uniformity of treatment. A few of the plates are in black and white; in the greater number, however, colour is used in proportions varying from the tinting of a simple leaf or flower to the full-blown coloured plate, such as that of *Disa uniflora* (plate 63). All are alike admirably clear, and include, in addition to the habit illustration, careful detailed drawings of the parts of the flower.

The species figured and described represent nineteen genera, but a large proportion are included in the typically South African genera, Disa, Satyrium, and Eulophia. Some are well-known species; a good proportion were discovered and have been previously described by Dr. Bolus, while a few, such as *Eulophia Pillansii* and *Mystacidium Aliciae*, are described here for the first time. Some are of special interest as representing rediscovered species. For instance, *Disa Telipogonis*, Reichenb. f., a remarkable little plant found by Berg on the summit of Table Mountain in 1816, was rediscovered in the same locality by Miss Kensit in 1904. The only other record of its occurrence was from the mountains in the Wellington district, where Dr. Schlechter found it in 1896, at a somewhat lower elevation.

A pleasing feature of Dr. Bolus's work is the readiness with which he gives credit wherever possible to those who have helped in his work either by sending specimens, or with their critical knowledge. Among these helpers may be mentioned, besides Miss Kensit, Dr. Schlechter, whose knowledge of the Cape orchids was perhaps second only to that possessed by Dr. Bolus, and Miss Alice Pegler, who has done good work

in the botanical exploration of the Kentani district, and to whom are dedicated the two new species of Mystacidium figured—her own discoveries. To these and others Dr. Bolus gives grateful recognition in his introductory note.

An index comprising a list of species and synonyms is placed at the end of the text matter, and a good portrait of the author as a frontispiece is a pleasing addition. A. B. R.

THE STUDY OF FIELD CROPS.

Southern Field Crops (exclusive of Forage Plants). By Prof. J. F. Duggar. Pp xxvii+579. Rural Text-book Series; edited by L. H. Bailey. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 7s. 6d. net.

AT a certain stage in his studies the agricultural student is called upon to consider crop-growing in its economic aspects, and he soon finds himself in a wide and rather indefinite field, where, in theory, his chemistry, botany, entomology, &c., ought to meet, and where the bearing of all the sciences on practical agriculture ought to be made manifest. In theory the student is to be directed in his studies of this branch of the subject by a man whose attainments in these several sciences is beyond reproach, and who has also a first-hand acquaintance with the economic problems involved. But in practice this ideal combination is never attained, and consequently the study of field crops goes in with agriculture, and is left entirely to the empiricist, no man of science having set up any claim to deal with them from the economic point of view.

Like other teachers of agriculture, Mr. Duggar is an empiricist; but he is an enlightened one, and makes liberal use of the data accumulated by his *confrères* on the science side. He deals, as one would expect, very fully with maize and cotton, to each of which some ten chapters are devoted, the rest of the book being occupied with the less common crops—wheat, oats, sorghum, rice, &c. The usual arrangement of the subject-matter is to begin with the structure of the plant; then to pass on to its races and varieties, the methods of breeding or improvement, the soils and fertilisers best adapted, the appropriate tillage and cultivation, and finally the insect and fungoid pests. Thus the whole field of science is covered, from chemistry and botany to entomology.

Considering how much such a task is beyond the powers of any one man, Mr. Duggar has done remarkably well. The purist in method, of course, might object to the empirical treatment of the subject, and feel dissatisfied with the numerous bald statements, such as "Insect pests [of oats] are the same as those of wheat, except that the oat is not attacked by the Hessian fly," just as the purist in language (and many others as well) might object to another statement—"*ensilage* is the verb, as 'to ensilage corn,' with the accent on the middle syllable." But these difficulties are inherent in the subject, and it would be unreasonable to judge the book from a point of view other than that from which it was written and will probably be used.

For in the meantime, while he is waiting for the true scientific treatment of crop husbandry to be developed, the student needs some one book in which he can find collected all the information he wants about ordinary crops. He is more concerned with the facts themselves than with their bearing on one another or on any central hypothesis. From this point of view Mr. Duggar's book is very good; there has obviously been a great deal of work expended in collecting the facts, and the references to the literature at the end of each chapter, if not entirely satisfying to the man of science, will at any rate put the student in touch with other work on the subject. In the present state of our knowledge the collection of the facts relating to the growth of crops is extremely necessary for further progress, and Mr. Duggar has contributed material that will be found distinctly useful.

As in the other members of this series, the book is well illustrated, and the pictures are well chosen, there being remarkably few of the ordinary useless field views. "An honest book," Dr. Bailey calls it in his introduction; ". . . these makers of observation text-books, that present the crops and the animals in their real and living details, will set going a great quiet movement to examine minutely the conditions of agricultural failure and success." E. J. RUSSELL.

PROPERTIES OF MATTER.

General Physics for Students: a Text-book on the Fundamental Properties of Matter. By E. Edser. Pp. ix+632. (London: Macmillan and Co., Ltd., 1911.) Price 7s. 6d.

IT is not often that a text-book, published under a familar title, presents so many novel and valuable features as Mr. Edser's latest production, "General Physics for Students." It is scarcely too much to say that with regard to contents and general mode of treatment the book forms a class for itself. By the collection of so much fresh material into one volume, Mr. Edser has made accessible to students many parts of physics, which, either from lack of time or initiative, they have hitherto been unable to appreciate. This has been done in no meagre fashion, the details, both experimental and theoretical, being consistently of a very comprehensive character.

The very care which has obviously been bestowed upon the work in order to suit it to the needs of students has, we think, been the cause of the one unfortunate feature of the book. This is the avoidance of the use of calculus notation—a procedure which the author seeks to justify in the preface. There is undoubtedly much to be said for such omission in the case of junior students whose teaching involves but rare recourse to calculus methods; but to continue the practice through a book of this kind is open to grave objections. The students who use the book may be divided into two classes—those sufficiently acquainted with calculus notation and methods, and those ignorant of them. The former class are liable to become annoyed at the repeated integration from first principles of the same function; the latter class may become accustomed to regard the laborious processes given as essential parts of the problems in

question. The author's reasons for following this method are not apparent, but we are tempted to believe that it is in order to conform with the regulations of the University of London, which still insist that the pass degree in physics should be obtainable without a knowledge of the calculus.

The earlier chapters of the book are devoted to the principles of mechanics, special attention being paid to oscillatory and gyrostatic motion. The simpler parts of the subject seem somewhat curtailed, but that is, perhaps, excusable in view of the very comprehensive nature of the book. Following chapters on gravitation and elasticity, we find surface tension very fully treated, and it is noticeable that the author very properly points out the inaccuracy of the statement often made, that the surface tension is equal to the surface energy per unit area. Chapters xi. to xiv. introduce subjects the inclusion of which renders this book unique. The author deals in a simple yet detailed and exact manner with the motion of fluids, including applications to the properties of vortex filaments and the waves on the surfaces of liquids. In the concluding chapter there is also to be found much that is new from the student's point of view. The consideration of the kinetic theory of gases is more complete in many respects than that which has usually been given, particularly with respect to the influence of the finite size of the molecules and the various methods of estimating their size and number.

As in Mr. Edser's other books in this series, the printing is excellent, and the heavy type used in the more important statements is very desirable. Good figures and diagrams form another pleasing feature. A wealth of examples (to which answers are given) should enable the student to become thoroughly acquainted with the principles described, and there is little doubt that the book, both from its general excellence and unique features, and notwithstanding the calculus methods referred to, will become almost indispensable to the students of physics.

MARINE ENGINES.

Marine Engine Design, including the Design of Turning and Reversing Engines. By Prof. Edward M. Bragg. Pp. 172. (London: Constable and Co., Ltd., 1911.) Price 8*s.* net.

IN this small book the author has endeavoured to describe methods by which the

"detailed design of the principal parts of marine engines can be determined, and has concentrated the results of several years of experience in teaching the subject of marine engine design to students of the University of Michigan."

Within these modest limits the volume should prove useful as a class-book for students, although it cannot be admitted that Mr. Bragg is accurate in the opinion, expressed in his preface, that

"most of the text-books on the subject of marine engines deal only in a general way with the subject of design, and particularly . . . as referring to the numerous coordinating parts of the modern marine engine."

On the contrary, many excellent text-books exist—in English, French, and German—which contain full discussions of design of details for marine engines and numerous examples drawn from actual practice. The distinctive feature of the book under review is really found in its exclusive devotion to details of design, whereas preceding text-books have been more comprehensive in scope, and as a consequence are larger and more expensive.

Prof. Bragg confines attention to marine engines of reciprocating types; he leaves untouched problems connected with steam turbines as applied to ship-propulsion, although these are undoubtedly of primary importance in present circumstances. Rules and specimen calculations are given for determining the dimensions of cylinders, the "cut-off" in the admission of steam, the length of stroke, and other particulars for engines of specified powers and given rates of revolution. Steam speeds, valve diagrams, valves, and valve-gear are treated at considerable length. Attention is directed also to methods for calculating the strengths of many of the principal fixed and moving parts of reciprocating marine engines; in some cases the rules for details of marine engines issued by the principal societies established for the survey and classification of merchant shipping are reproduced.

The last two sections of the book contain a full discussion of the details of design for auxiliary engines fitted for the purpose of turning the crank-shafts over—when valves are being set or when the main engines are being overhauled—and of designs for small engines used for reversing the main engines in steamships. About one-sixth of the total space in the volume is devoted to these subjects, although they are unquestionably of less relative importance than must be assigned to other matters, to which less attention has been devoted by the author. His hope and expectation, as expressed in the preface, are that by keeping the book "free from the descriptive part of the subject it will fill a decided void" and be "much more readily available" than other text-books "for the particular use for which it is intended." The majority of students will, in all probability, favour the use of text-books which are less restricted in aim, and are richer in descriptions and illustrations of various types of engines. This opinion, however, in no sense reflects on the manner in which the author has done his work; and, of course, he is entitled to form and act upon his own estimate of the kind of text-book likely to prove of most service to students of marine engineering.

W. H. W.

OUR BOOK SHELF.

Puppets: a Work-a-Day Philosophy. By George Forbes, F.R.S. Pp. ix+183. (London: Macmillan and Co., Ltd., 1911.) Price 3*s.* 6*d.* net.

THIS is a philosophical sketch, or skeleton, clothed upon with the human interest of a story. A party of happy and well-to-do people are staying at a Scottish castle, and James Gordon expounds to them his philosophical views. These are of the idealistic kind, which may roughly be called Berkeleyan, and Gordon develops them very ingeniously, making some use of the modern psychological doctrine of the subconscious. All our knowledge of the world is a mental knowledge; all "things" are *thoughts* or, at least, cannot

be proved to be anything further. But this does not destroy anything of importance, or reduce cosmos to chaos, as "common-sense" might suppose. The world of each one's experience is real enough in each one's own mind, and there is no gain in attributing to it any material kind of reality. The concordance, in a general way, of my experience with your experience, is explained by supposing a universal-thinking or dominant Self who is thinking the world. Or, as Berkeley would say, the universe exists as the thought of God.

Our human selves are greater than their present manifestations. For educative purposes, each of us has been given a puppet to work and manage (our bodies, namely), and we can only express ourselves very inadequately through this dull mechanism. Indeed, some of the faculties we are proud of are the results of our limitations—for instance, reasoning. "There is simply no limit to what the mind can think of were it not spoilt by reasoning." Witness the marvellously accurate movements of the fingers in piano-playing, movements which must be supposed to be controlled by intelligence, but which certainly could not be performed at that speed if the slow consciousness had to superintend every muscle-twitch. Similarly with calculating prodigies, who multiply six figures by six figures, not in the way we multiply, but by a sort of instinct.

This philosophy, of course, includes some kind of immortality, for, though the body-puppet dies, the self which worked it is not thereby rendered any less alive; and it goes on experiencing, in other forms, probably not spatial and temporal.

The psychology of the book is quite admirable, and even its farthest-reaching speculations (which are put forward as such, and not as dogmas) are logical and justifiable, from the idealist's point of view. And the philosophic pill is nicely sugared with two love stories which end as happily as the most benevolent reader could desire. J. A. H.

The Relative Volumes of the Atoms of Carbon, Hydrogen, and Oxygen, when in Combination. By Hawksworth Collins. Pp. 107. (London: Morton and Burt, Ltd., 1911.) Price 7s. 6d.

THE author's views on the volume relations of the atoms in chemical combination differ fundamentally from those of previous observers. The present book deals exclusively with liquids containing carbon, hydrogen, and oxygen. At 15° and atmospheric pressure an atom of hydrogen, when in combination with an atom of carbon, occupies one of four relative volumes, viz., 15·25, 12·22, 9·95, and 5·76. The volume of any one atom of hydrogen is determined by the portion of the carbon atom to which it is attached. There are four portions of the carbon atom, corresponding with the valencies, and the theory implies that the valencies are unequal. The relative volume of the carbon atom is generally 0·71, but in certain circumstances expands to 8·0. From this it follows that the volume of a hydrogen atom may be twenty times that of a carbon atom. Oxygen has three volumes, 2·51, 4·45, and 7·53, depending on the nature of the compound and the position of attachment to the carbon atom.

This remarkable theory of atomic volumes is explained within the limits of four pages, and the remainder of the book is occupied with the graphic formulæ of 100 organic compounds (alcohols, ethers, &c.). In these formulæ the carbon atoms are represented as oblongs divided into four portions, and the positions of attachment and the relative volumes of all the atoms are shown.

The author states that "the theoretical and experimental specific gravities never differ by more than 0·001, although different experimentalists seldom agree to more than two places of decimals." It is difficult to see how these statements can be reconciled. Moreover, the author has the choice of nine volumes for the three elements, whereas Kopp obtained a fair agreement between observed and calculated values for molecular volumes at the boiling point with one volume each for carbon and hydrogen and two volumes for oxygen; it is evident, therefore, that an agreement between observed and calculated values on the former basis can scarcely be regarded as conclusive evidence in favour of the author's theory. The theoretical discussion of the subject is quite inadequate, and it is to be hoped that some of the more obvious omissions will be repaired in the later volumes on the subject which are promised.

Forest Flora of the Siwalik and Jaunsar Forest Divisions of the United Provinces of Agra and Oudh, being a revised and enlarged edition of the Forest Flora of the School Circle, N.W.P., with Analyses, compiled for the use of the Students of the Imperial Forest College, Dehra Dun. By U. Kanjilal. Pp. xxix+457. (Calcutta: Government Printing Office, 1911.) Price 1.14 rupees for public; 1.4 rupees for students.

TEN years have elapsed since the first edition of the "Forest Flora of the School Circle, N.W.P.," was published; meantime the division of the School Circle has received other names for both forest and administrative purposes, which are given in the revised title, and the author has noted certain alterations and emendations that are desirable. The glossary has been revised, family names have been changed in accordance with the Vienna rules, an important addition has been made in the shape of an analytical synopsis of the orders and families which provides ampler details for their determination, and a general revision of the flora has been effected. The teaching experience of the author has suggested but few changes in the list of species described. Only two of the additional species incorporated are trees, *i.e. Diospyros Kanjilali* and *Linociera intermedia*; the former was described in 1905 by Duthie from material supplied by the author. These alterations will serve to increase the usefulness of this pocket flora.

Wilson's Folding Globe. Circumference 40 inches. (London: George Philip and Son, Ltd.) Price 7s. 6d. net, in cardboard box.

THIS ingenious device will prove of excellent service to teachers of geography in assisting them to correct the misleading ideas which are apt to arise in the minds of young pupils by the exclusive study of flat map projections. The mere fitting up of the globe, with the aid of the simple accessories provided, will impress upon the beginner the distortion entailed by the representation of a spherical surface on a plane. When placed flat, the "gores," which when arranged form the globe, make up an equal scale map of the world. There is sold with the folding globe a map of the world on Mercator's projection, so that a proper understanding of its advantages and disadvantages may be secured by comparing it with the equal scale map.

A Text-book of Geography. By G. Cecil Fry. Second edition. Pp. xxi+468. (London: W. B. Clive, University Tutorial Press, Ltd., 1911.) Price 4s. 6d.

THE first edition of this book was reviewed in NATURE for March 11, 1909 (vol. lxxx., p. 31). In the present edition more than thirty new maps and diagrams have been added, as well as a number of climatic data for the principal divisions of the world. A new appendix of some 350 examination questions has been introduced.

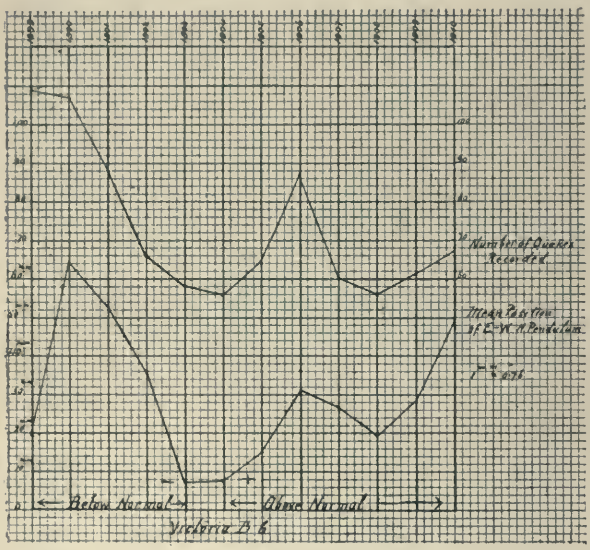
LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Irregular Long-period Changes in Level.

AT the Portsmouth meeting of the British Association Mr. F. Napier Denison contributed a paper on changes in level observed with a horizontal pendulum at Victoria, B.C. Observations commenced in January, 1899, and extended over the next eleven years. For the most part these refer to changes in level in an east-west direction. Like observers in other parts of the world, he found diurnal, annual, and other changes, all of which can be referred to epigenic influences.

Over and above these Mr. Denison pointed out that the pendulum did not annually return to its normal position; for irregular periods varying between twelve and thirty months the zero might travel eastwards, after which it would make a greater or less excursion towards the west. But here comes the interesting point. A curve of these wanderings very closely agrees with one representing the annual frequency of world-shaking earthquakes, which



have been most numerous when the pendulum was farthest removed from its normal position, whether this was to the east or west. The accompanying curves by Mr. Denison are self-explanatory.

With the object of throwing further light on these observations it would be of interest to learn whether these long-period changes in level, and, I may add, in azimuth, have been recorded at observatories which have piers on rock foundations, particularly in districts where there is reason to suppose rock folding may still be in progress. Such observatories may perhaps be found in Switzerland, Italy, the Balkans, North India, and the American and Asiatic shores of the Pacific. I have not, however, been able to find a catalogue which gives information about the foundations of astronomical observatories.

An excellent *résumé* relating to changes in the vertical is given by Sir G. H. Darwin in a report to the British Association (1882). What is now required is a *résumé* since 1899, from which date we possess a fairly complete catalogue of world-shaking earthquakes, each of which, there is reason to suppose, may be regarded as the announcement of a general relief in seismic strain, and as one earthquake may beget another, they frequently take place in widely removed districts at about the same time. If a megaseism means a relief of strain in the crust of our world, can astronomers throw any light upon its growth?

All who are interested in earth physics would like to know whether evidences of long-period changes in the vertical exist, particularly in the direction of the dip of strata on which their observatories are situated.

Shide, Isle of Wight, England. JOHN MILNE.

Solar Eclipse—April, 1912.

A FEW years ago I read a short paper before the British Astronomical Association, in which I suggested that certain eclipse observations should be made, not at the centre line of the path of the shadow, but as near as possible to its two edges; and seeing that the forthcoming eclipse is unsuitable, on account of its short duration, for the usual observations, I hope that the astronomers of Europe will devote their attention to determining the position and width of the shadow. If they can do this with the exactitude which I anticipate, then, in a single day, full information will have been collected with which a profile of the earth's surface can be drawn along a line extending from Portugal through Spain, France, Belgium, Holland, Germany, and Russia to Siberia, which profile would have the advantage that it would be unaffected by local variations of gravity.

My suggestion is that enlarging cameras should be attached to the observing telescopes, and that images of the northern and southern edges of the sun and moon should be thrown on sensitive films, which would have to be moved in a north and south direction (say at the rate of 1 mm. per second). An observer stationed outside the shadow would obtain a negative image consisting of a black band with one gap at either edge; the horizontal (east and west) distance between the edges of these gaps would be the width of the chord on the sun's disc which is traversed by the moon's north or south edge; the vertical (north and south) distance between the gaps would represent the time taken in traversing this chord. An observer stationed inside the moon's shadow would obtain a negative image, which would be a black band crossed by a white "bend," the horizontal width of which would represent the length of the chord on the moon's disc traversed by the edge of the sun, and the vertical distance would represent the time taken in traversing this chord.

The length of the chord being known either by measurement or by calculation from the time, the overlapping of the northern or southern edges of the sun and moon could easily be calculated. The moon's apparent semi-diameter is about 1000″, and its actual semi-diameter about 1000 miles. If the enlargement be such that 1 mm. = 1″, then if one of the observers should find that the length of the chord is, say, 100 mm. on the film, equal to 100″, or 100 miles, then the amount of overlap is $50^2 : 2000 =$ 1·25 mm., ″, or miles, and he will know that he was stationed one and a quarter miles, or 2 kilometres, from the edge of the shadow. A more fortunate observer, who may obtain a length of chord of only 10 mm., would know that he was stationed at one-eightieth of a mile from the edge. If, as seems likely, the photographic records can be measured with an accuracy of one-fifth millimetre, then the latter observer will feel sure of his position to within one two-thousandth of a mile, or, say, to within 1 metre.

As the angle at which the shadow strikes the earth will nowhere be less than, say, 50°, it is evident that a small difference of level of only a few metres between two observers would make a perceptible difference in their photographic records, and these would, therefore, afford the means for accurately fixing their relative heights along a line extending from Portugal to Siberia. Future eclipses, both total and annular, would enable a network of such profiles to be determined not only across continents, but also across oceans. C. E. STROMEYER.

"Lancefield," West Didsbury, October 25.

Khartoum for an Observatory.

AT a time when search is being prosecuted in northern Africa (NATURE, September 21, p. 393) for an observatory site, it may not be out of place to direct attention to the merits of the Khartoum vicinity, so far as this can be done by one who is not an astronomer. Its features may be enumerated as follows:—

Position.—Latitude 15° 36′; it is some degrees nearer

the equator than Salisbury in Rhodesia. The importance of a low latitude has been illustrated by the success of Helwan Observatory in obtaining the earliest photograph of Halley's comet, owing to the longer night near Cairo in summer as compared with Greenwich or Heidelberg. This advantage would be still further marked in the case of Khartoum, some $14\frac{1}{4}°$ south of Helwan, or relatively about as far as Barcelona is from Edinburgh.

Altitude.—Precise determinations have been made by levelling, and the land near the river has been found to stand about 385 metres above sea-level.

Climate.—So far as I am aware, the "seeing" qualities of the atmosphere have not been tested. Ordinary experience shows that it is remarkably clear, and it is no uncommon thing near the Italian boundary in these latitudes to see Jebel Kassala (4400 feet) and some of the Eritrean hills at distances up to a hundred miles. These districts are at no great height above sea-level, and the clearness of vision must in large measure be due to the pureness and homogeneity of the air.

Relative humidity is a factor presumably of great importance as regards the "seeing" qualities of the air; and those interested may refer to Captain Lyons's "Physiography of the Nile and its Basin," where they will find the data for Khartoum and many other stations concisely summarised. More recent data are available in the annual meteorological reports, &c., published by the Egyptian Survey Department. Suffice it to say that the mean annual relative humidity is 31 per cent., and this figure is only exceeded for three months in the year. The Khartoum observations have been made within a short distance of the river, and no doubt the humidity results are higher than would have been obtained at a station a mile or two away. The air is often dry enough, even near the river, to desiccate moist calcium chloride. There are very few cloudy nights.

During the summer months violent dust-storms occur, but these are generally of short duration. Situated on the southern edge of the desert, it has a rainfall of about 6 inches a year, almost confined to the months of August and September. Temperature conditions are extreme, but owing to the intense dryness heat is seldom oppressive to the individual.

Communication.—Several mails a week carry letters to London in nine or ten days, and the outward journey can be done in eight and a half days. The railway to the Red Sea enables goods from outside to reach Khartoum with only a single handling at Port Sudan.

It seems improbable that there is any other locality in an equally low latitude offering the advantages of a clear, dry atmosphere combined with a fair altitude and such ready means of communication with European centres of learning. As an actual site in this vicinity the Abu Meru Hills may be suggested, as rising about 100 metres above the river at a distance of some eight miles north-west from Omdurman. The place is far enough to avoid any local humidity due to the river, as well as the dust-raising traffic converging on the towns. The prevalent winds are from the north and north-west, and traverse hundreds of miles of unbroken desert before reaching the hills.

In conclusion, I have to thank Mr. Rolston for directing my attention to the search being undertaken by the French Geographical Society. Our friends across the Channel have extensive possessions in northern Africa, and no doubt these have first claim for consideration; but if they are unable to exploit Khartoum, perhaps it may be kept in view and tested when munificence can be found to provide for the equipment and maintenance of a new observatory.

G. W. GRABHAM.

Khartoum, Sudan, October 15.

The Scientific Misappropriation of Popular Terms.

I ENTIRELY agree with Dr. Harmer (NATURE, October 26) that the extension of priority to groups larger than genera is undesirable, and the use of the word insect should be judged solely by practical convenience.

If the restricted use of the word insect were as generally accepted as that of deer there would be no objection to its use. I understand, however, that the use of deer for small mammals was abandoned in Middle English, and that the phrase "mice and rats and such small deer," quoted by Dr. Harmer, was intended by Shakespeare and later authors to be a joke, like the railway porter's classification of the tortoise as an insect.

The same explanation is not available for the remark in Prof. Adam Sedgwick's "Text-book of Zoology" (vol. i., p. 502) that "all spiders are predaceous and suck the juices of other insects."

I cannot agree with Dr. Harmer that the word insect is, or ever has been, generally used in the restricted sense either in popular literature or in technical works other than zoological. For example, agriculturists always seem to speak of insect in the wider sense, and agricultural literature generally does the same. Nor do I find any agreement on the subject among zoologists, and the tendency seems to be for them to abandon Insecta as a class name in favour of Hexapoda. Sir Ray Lankester expresses the matter admirably in the new edition of the "Encyclopædia Britannica." He rejects Insecta as the class name of the "so-called 'true insects,'" and regrets that Lamarck, who invented the "very appropriate name Hexapoda," did not insist on it; and "so the class of Pterygote Hexapods came to retain the group-name Insecta, which is, historically or etymologically, no more appropriate to them than it is to the classes Crustacea and Arachnida." He refers with obvious disapproval to "the tendency to retain the original name of an old and comprehensive group for one of the fragments into which such group becomes divided by the advance of knowledge, instead of keeping the name for its logical use as a comprehensive term, including the new divisions, each duly provided with a new name" (Sir Ray Lankester, "Encyclop. Brit.," vol. ii., 1910, p. 673).

Those, therefore, who use the word insect in its older and etymologically more correct sense have the support of high zoological authorities.

4 Park Quadrant, Glasgow, October 28.

The Colour of a Donkey.

ON October 5, at 7 p.m., the moon being high up and almost obscured by a thick high haze, giving a diffused ground light with no shadows, I was crossing an open field by a footpath. The field is about a quarter of a mile across, and the hedges all round it, with tall elms, were marked out in broad dark masses. The grass, dried by the hot summer, is straggly and grey, with short green undergrowth. There were a number of cows—red and red and white—scattered over the field, visible in the dim light up to 80 yards by measurement. One could apparently see everything within that radius.

I was brought to a halt by hearing an absolutely invisible animal noisily cropping the grass a few feet away. On going nearer I found a grey donkey. On his starboard quarter at 4 yards' distance his dark head appeared as a moving blur, but "stern on" at that distance he was completely invisible—an "airy nothing"—though, like Polonius, "at supper." It was most extraordinary to hear the animal feeding and to be unable to see a vestige of him. At 2 yards' distance he was a mere ghost. The lighter under-colour of the ventral surface certainly diffused what light there was, after the manner of the vanishing duck in the Oxford Museum. That may be partly the explanation.

Returning by the same path at 7.30, I tried by walking across the field in every direction to find the donkey, but failed, though the cows were all plainly visible, feeding or lying down, and the donkey was in the field all night.

The striped zebra, invisible in the moonlight, is cited as an example of protective coloration. I merely record the above facts without venturing upon any explanation of them.

There is an old rhyme describing the palpitations of a villager followed at night across a field by an invisible creature with audible footsteps—

"And much he feared that dreadful ghost
Would leap upon his back."

That was also a donkey, and the rhyme, like Gilpin's ride, may be the jocular record of a fact. My donkey was ghostly enough, and suggests possibilities.

Waterstock, October 24.

E. C. SPICER.

Non-Euclidean Geometry.

As many mathematicians give very little thought to the theory of sets, it is perhaps worth while dwelling for a moment on Dr. Sommerville's possibly misleading remarks in NATURE of October 5. He, quite correctly, points out the one-one correspondence between the aggregates of integral numbers 1, 2, 3, &c. (n), and even numbers 2, 4, 6, &c. ($2n$). Thus the part appears equivalent to the whole. This statement loses the character of a paradox to all who will bear in mind that the notion of "the part cannot equal the whole" has its origin in the contemplation of *finite* quantities.

Again, the sets of numbers of the form $4n$ and $4n+2$ constitute aggregates of the same type; they are equivalent to each other as well as to n itself and $2n$. I fail to see that Dr. Sommerville shows the part to be larger than the whole. An aggregate A would be larger than A′ if A contained a set equivalent to A′, while A′ does not contain a set equivalent to A.

HAROLD M. SADOW-PITTARD.

SS. *Caledonia*, October 14.

IN drawing a parallel between Legendre's proof and the paradox concerning infinite aggregates, I had not thought it necessary to point out the fallacy, which consists, as in Legendre's proof, of transferring to infinities notions which are derived from a study of finite magnitudes.

Of the two propositions, a part is (1) equal to, and (2) greater than, the whole; the one is just as much a paradox as the other until the meaning of the terms equal, greater, and less has been extended and modified for infinite aggregates; and the proofs which I gave are equally in accordance with notions derived from finite aggregates. Neither of them was intended as a valid proof, though the first happens to be in agreement with the usual extension of the meaning of equivalent. D. M. Y. SOMMERVILLE.

The University, St. Andrews, October 23.

Dew-ponds and the Dry Season.

WITH reference to the remark in NATURE of October 26 (p. 559), I paid a visit to the Chanctonbury Dew-pond about the end of last August, and was surprised at its flourishing condition.

The water-level was, of course, much below the normal, and the surrounding water plants were much trodden under by sheep and cattle. There still remained, however, a good fringe, and the usual pond plants seemed to be in a satisfactory state. I could not get to the water's edge owing to the moist and boggy nature of the ground, usually submerged.

Some other dew-ponds met with in the course of a few days' walk west of Chanctonbury were quite dry, so far as I remember. J. P. CLATWORTHY.

University College, Reading, October 30.

CHARLES DARWIN'S EARLIEST DOUBTS CONCERNING THE IMMUTABILITY OF SPECIES.

IN view of the great revolution in scientific thought which was inaugurated by the publication of the "Origin of Species," the story of the evolution of ideas in the mind of its author must always have a deep fascination for the student of the history of science—and the question of the nature of the initial stage of that evolution is one especially worthy of attention.

In his autobiography, Charles Darwin has declared his belief that, before leaving England for the memorable voyage in the *Beagle*, he was quite indifferent to any speculations upon the subject of evolution—and this in spite of his admiration for his grandfather's "Zoonomia" as a literary production.[1] Now concerning the exact period in his life when Darwin ceased to feel this indifference, and had his interest aroused by that "mystery of mysteries"—to the solution of which his whole after-life was to be devoted—there have been very marked differences of opinion.

Huxley stated his conviction to be that no really important fruits of the observations made during the voyage of the *Beagle* could have been gathered by the ardent but untrained young naturalist until after he reached England, and had the opportunity of consulting specialists concerning the specimens which had been sent home by him from time to time.[2] But, on the other hand, Dr. Francis Darwin and Prof. Seward maintain that during the voyage, and especially towards its close, when the Galapagos Islands were visited, Darwin's observations and his meditations upon them had already begun to bear fruit, and had led him to lose his absolute faith in the immutability of species.[3] I am myself convinced, as the result of a careful consideration of letters written at the time, that *very early indeed in the course of the voyage* certain observations and reflections had given rise in Darwin's mind to *serious misgivings* concerning the fixity of species, although, writing nearly fifty years afterwards, he dismissed them lightly as nothing more than "*vague doubts*."

It was this statement in Darwin's correspondence to which Huxley appears to have attached very great importance. It occurs in a letter to Dr. Zacharias and is as follows:—

"When I was on board the *Beagle* I believed in the permanency of species, *but as far as I can remember, vague doubts occasionally flitted across my mind*."[4]

It should be borne in mind, however, that as these lines were written as late as 1877, to one of his very numerous casual correspondents, we may not improbably infer that Darwin penned them somewhat hastily and without any deep thought or reflection concerning the interpretation that might be put upon them if published. For it must be remembered that nearly twenty years before this he had written and *printed* the following:—

"When on board H.M.S. *Beagle* as naturalist, I was *much struck* with certain facts in the distribution of the inhabitants of South America, and *in the geological relations of the present to the past inhabitants of the continent*."[5]

Seeing that these words form the first sentence of the introduction to the "Origin of Species," and must therefore have expressed the result of very deliberate thought and consideration, that they would certainly have been frequently scanned by the author before publication, and that they are repeated without change or qualification in every succeeding edition of the book, it is undoubtedly only fair to attach far greater weight to them than to a sentence hastily indited to a casual correspondent so many years afterwards.

In that marvel of candid introspection, the "Autobiography," Darwin wrote in 1876 as follows:—

"During the voyage of the *Beagle* I had been *deeply impressed* by discovering in the Pampean formation great fossil animals covered with armour like that of the existing armadilloes."[6]

And this he enumerates as the *first*, though *not the most important*, of the observations which turned his thoughts in the direction of evolution during the voyage. When writing to Haeckel in 1864 he says:—

"*I shall never forget my astonishment* when I dug out a gigantic piece of armour like that of the armadilloes."[7]

Owing to a singular blunder, for which Darwin was in no way responsible, I shall have to point out that

the significance and importance of this *fateful* discovery—for such I believe it to have been—has to some extent been overlooked; but concerning the time and place that it was made, and all the circumstances connected with it, we fortunately have ample information.

During the first six months that he spent in South America (March to September, 1832), Darwin tells us that he had "procured a nearly perfect collection of mammals, birds, and reptiles" in the districts around his two great centres of work at this time, namely, Botofogo Bay, near Rio de Janeiro, and Maldanado, near Monte Video.[8] In doing this he could not fail to be greatly struck by the peculiarities of the fauna, with its sloths, ant-eaters, and armadilloes. From the journals both of Fitzroy and Darwin, we learn that questions concerning the several species of armadilloes and their geographical range were at this time engaging their attention.[9]

It fortunately happened that, during the autumn of 1832, the *Beagle* was delayed for some weeks in Blanco Bay. The energetic young captain (Fitzroy was at this time twenty-seven years of age, only four years older than Darwin himself), finding that, in his own ship, he could not safely survey the shallow waters of the South American coast, purchased, at his own expense, two tiny undecked sealing craft and placed them under the command of two of his officers who volunteered for the service. While the alteration, refitting, and rigging of these dirty little vessels was in progress, the *Beagle* was delayed at her anchorage, and Darwin found an opportunity of which he took splendid advantage.

Near Punta Alta, on the shores of the Bay of Bahia Blanco, there is a cliff about 20 feet high extending for the distance of a mile; the beds exposed in this cliff consist of false-bedded gravel, sand, and marl, in which were many shells which Darwin recognised as belonging to existing species. But in the midst of these sands and gravels could be seen a lenticular bed of red mud, in which the bones of great quadrupeds occurred in such abundance that remains of nine large mammals were disinterred from an area of 200 square yards.[10]

Under the date of September, 1832, Captain Fitzroy wrote in his journal as follows:—

"My friend's" (Darwin's) "attention was soon attracted to some cliffs near Point Alta, where he found some of those huge fossil bones, described in his work, and notwithstanding our smiles at the cargo of apparent rubbish which he frequently brought on board, he and his servant used their pick-axes in earnest,. and brought away what have since proved to be most interesting and valuable remains of extinct animals."[11]

Doubtless, while his other shipmates were content with exhibiting mild amusement at the eagerness of "the Flycatcher," as Darwin was called by them, the martinet first-lieutenant, as is recorded in the "Life and Letters," would be moved to wrath by the state to which his decks were being reduced by these strange proceedings, and driven to employ choice nautical language concerning "the d——d beastly devilment," not forgetting to add, "If I were skipper, I would soon have you and all your beastly mess out of the place."[12]

It was probably on this occasion that Darwin experienced those pangs of "despair with which he had to break off the projecting end of a huge, partly excavated, bone, when the boat waiting for him would wait no longer"—a sorrow which, as his son tells us, he often recalled and spoke of in after-life.[13]

We must bear in mind that Darwin collected from this treasure-house of mammalian remains at Punta Alta on two different occasions, first in September, 1832, and secondly in August, 1833.

That it was on the *first* of these occasions "the gigantic piece of armour like that of the armadilloes was procured" is fortunately proved by a letter written by Darwin to Henslow, dated November 24, 1832, and communicated to the Cambridge Philosophical Society before the *Beagle* had returned to England.[14] The opportunities which the young naturalist then enjoyed of having boats and men at his disposal to transport these great bones of the Pampas formation to the ship, appear to have been unique.

In the very important letter to which I refer, Darwin speaks of finding "fragments of at least six different animals," including "a large surface of the osseous polygonal plates, which 'late observations' (what are they?) show belong to *Megatherium.*" In writing thus, Darwin was evidently, to some extent, the victim of a mistake into which naturalists had been betrayed at the beginning of last century. Whether, in using the words, placed between inverted commas by him, Darwin was quoting from some author, I have vainly endeavoured to discover by an examination of the books which he would probably have in his little library on the *Beagle*; but the query, which he puts in brackets, clearly shows that he suspected that an error had been committed. And this conclusion is confirmed by the sentence which follows:—

"Immediately I saw this I thought they must belong to an enormous armadillo, living species of which genus are so abundant here."

The history of the origin and spread of the idea that the dermal armour of the Glyptodonts belonged to the Megatherium is a very curious one.

It has been suggested that Dr. Buckland was responsible for the unfortunate error,[15] but the passage quoted in support of this view is taken from the "Bridgewater Treatise," which was not published until 1836, and indeed contains a reference to Darwin's own work in South America. Buckland, like other geologists and zoologists of that day, merely followed the lead of Cuvier in this matter.

The remains of the gigantic fossil sloths of South America had found their way to Europe before the end of the eighteenth century, and both Megatherium and Mylodon were described by Cuvier in his "Ossemens fossiles" in 1812. But while preparing the fifth volume of the second edition of that great work in 1823, he received from a colleague, the botanist August de Saint-Hilaire, a letter sent with specimens from South America, by D. Damasio Larranãga, curé de Montevideo. This letter, apparently without being carefully scrutinised by Cuvier and his assistants, was printed in a footnote,[16] and contains the words "Je ne vous écris point sur mon dasypus (Megatherium, Cuv.)." The worthy priest, who was evidently not a zoologist, confounded Dasypus (the armadillo) with the Megatherium; and, strange to say, Cuvier not only allowed the passage to stand, but added the suggestion that Megatherium might have possessed bony armour like the armadillo, and that he awaited impatiently further information on the subject from Larranãga. As bones of the giant sloths from South

America were often accompanied by portions of the bony armour, which occur in the same deposit, it is perhaps not surprising that the erroneous identification was caught up and repeated in other works on the subject.

It was not until 1840 that Owen in this country and Lund in Germany established the existence of the several genera of the Glyptodontidæ, and showed that these bony plates really belong to extinct forms allied to the armadilloes. It is therefore very interesting to find that the "untrained" naturalist of twenty-three years of age had divined the real truth on the subject so long before.

The specimen which excited such intense interest in Darwin's mind was described by him in 1846, after consultation with Owen, as follows:—

"A double piece, about three feet long and two wide, of the bony armour of a large Dasypoid quadruped, with the two sides pressed nearly close together: as the cliff is now rapidly washing away, this fossil was probably lately much more perfect; from between its doubled-up sides, I extracted the middle and ungueal phalanges, united together, of one of the feet, and likewise a separate phalang: hence one or more of the limbs must have been attached to the dermal case when it was embedded." [17]

This fine specimen, which would undoubtedly have been of great historical interest, from the effect it produced on the young naturalist's mind, is unfortunately no longer in existence. Darwin says "It was so tender that I was unable to extract a fragment more than two or three inches square." [18] Owen, in his memoir on the fossil bones sent home by Darwin, describes and figures two small fragments—"the portions of the tesselated bony dermal covering of a Dasypoid quadruped," and these are identified as belonging to the specimen in question by the statement that they "were discovered folded round the middle and unguel phalanges," which are also figured on the same plate.[19]

As evidence of the special interest which Darwin attached to this discovery, it may be mentioned that he at once sent home a fragment of this (or of a similar specimen) to his family, for we find him writing to his sister Catherine, on May 22, 1833:—"I am quite delighted to find the hide of the Megatherium" (he uses the term by which such specimens were then generally known) "has given you all some little interest in my employments." [20]

Now, in order to appreciate the extraordinary effect of this discovery on young Darwin's mind, we must remember what were the opinions current among geologists when it was made. The views of Cuvier at that date were regarded as not less authoritative in geology than they were in zoology, and in the introduction to his *magnum opus*, the "Ossemens fossiles," the opinions of the great comparative anatomist were pronounced with no uncertain note. He contended that each geological period must have been brought to a close through the sweeping out of existence, by a great cataclysm, of all plant- and animal-life, this being followed by the creation of a perfectly new assemblage of living beings. Cuvier's teaching was made as widely known in this country as it was on the Continent, for Jameson issued a number of editions of a translation of the famous introduction, under the title of "An Essay on the Theory of the Earth"; and, as von Zittel justly remarks, "Cuvier's catastrophic theory was received with special cordiality in England." [21] By none certainly was it adopted more unreservedly than by Darwin's teachers and friends, Henslow and Sedgwick.

17 "Geological Observations in South America" (1846), p. 84.
18 *Ibid.*, p. 86.
19 "Zoology of the *Beagle*," "Fossil Mammalia,' plate xxxii., and description.
20 "Life and Letters of Charles Darwin," vol. i., p. 245.

Among the books in Darwin's library, now piously preserved at Cambridge, is a copy of the fifth edition of the translation of Cuvier's "Essay," bearing the date of 1827,[22] and I think there can be no doubt that this book was one of those constituting the little library of reference in the chart-room of the *Beagle*, where Darwin worked and slept. Nor can there be any hesitation in concluding that with the contents of this book he would be thoroughly familiar.

This being the case, Darwin found himself confronted at Punta Alta with the two startling facts which he so clearly indicates in his letter to Henslow.

First, the bones of gigantic and undoubtedly extinct mammals were seen to be associated in the same deposit with shells of living species. He tells Henslow at the time, "They" (the bones) "are mingled with marine shells which appear to me identical with what now exist." (He, in fact, collected twenty-five species, all of which D'Orbigny afterwards pronounced to be still living.) How, on Cuvier's theory, could such a state of things arise? The cataclysm that destroyed the mammalian must surely have been equally fatal to the mollusca!

But the *second* fact was even more striking and significant. Not only did Darwin obtain the armour of "an enormous armadillo," but among the other remains he identified the jaw of another of the Edentata, and the teeth of rodents similar to those now living in the district.[23] His recent collections had made him familiar with the peculiar mammalian fauna of South America, and the striking characters which distinguish it from that of all other portions of the globe, and here, he states, was evidence before his eyes that the mammals of the period immediately preceding our own, though differing in being more gigantic, presented a striking family likeness to them. This was a fact quite inexplicable on the theory of wholesale destructions and brand-new creations, but most suggestive, and capable of simple explanation, if the recent forms were descended from the fossil ones, or both were representative of common ancestors.

When Charles Darwin arrived home in 1836, and engaged in the preparation of his journal for publication, he found that almost simultaneously with his own discovery a similar one had been made with respect to the Australian continent. Clift had identified a number of bones collected in caves in that island as belonging to extinct marsupials, and Jameson had pointed out the significance of their relations with the existing fauna.[24] There can be no doubt, however, that Darwin was quite unaware of this publication while he was in South America, though he refers to it in writing up his journal. Facts like these, so familiar to us at the present day, were then quite novel.

But it is by no means improbable that the mind of the young naturalist was in a specially receptive condition, when it encountered the shock of this important discovery. Darwin has again and again insisted on the revolution produced in his mind on geological questions by the study of the first volume of Lyell's "Principles of Geology," which he took

21 "History of Geology and Palæontology" (English translation), p. 141.
22 "Catalogue of the Library of Charles Darwin," p. 19.
23 "More Letters of Charles Darwin," p. 12.
24 "On the Fossil Bones found in Bone Caves and Bone Breccias in New Holland," *Edinb. New. Phil. Journ.*, vol. x. (1831), pp. 390–7. In this paper the list of species is by Clift, but the remarks are by the editor, Jameson. The arguments are somewhat weakened by the larger marsupial bones having been mistaken for those of elephant or rhinoceros. It is remarkable that most authors, including Darwin himself, give Clift the credit for the generalisations, but this is not borne out by an examination of the paper.

with him from England. In his dedication of the second edition of his "Journal," Darwin wrote, "The chief part of whatever scientific merit this journal and the other works of the author may possess has been derived from studying the well-known and admirable 'Principles of Geology.'"[25]

In a letter to his friend, at the same time, Darwin clearly explains the nature of his indebtedness to the "Principles." He says, "Those authors . . . who, like you, educate people's minds as well as teach them special facts, can never, I should think, have full justice done them except by posterity, for the mind thus insensibly improved can hardly perceive its own upward ascent."[26] And shortly before this he had written to Leonard Horner, "I have always thought that the great merit of the *Principles* was that it *altered the whole tone of one's mind*, and therefore that, when seeing a thing never seen by Lyell, one yet saw it partially through his eyes."[27]

It has been pointed out, both by Huxley and Haeckel, that when Lyell had completed the first volume of his great work he had arrived at the logical conclusion that the same principle of continuity or uniformity which he had demonstrated for the inorganic world must apply also to organic nature and even to man. This is clearly shown in the correspondence that has been published,[28] which also makes it manifest that some among Lyell's contemporaries who thought deeply on the subject could not avoid the same conclusion. Sedgwick clearly perceived this, and it moved him to rage and to making wild charges of "infidelity." Whewell saw it too, and shrank from accepting Lyell's doctrines because he could find no border-line between what he called "uniformitarianism" and evolution; but Herschel appears, at the time, to have been ready to go as far as Lyell himself. And the young naturalist on board the *Beagle*, did he begin to perceive, however dimly, "through Lyell's eyes" that evolution could not stop with the inorganic world? We have no evidence on this point; we can only conjecture it as possible.

This much, however, is certain, that Darwin, after completing his excavations at Punta Alta, returned to Monte Video, and among the articles sent from home which were awaiting him there, found the second volume of the "Principles," and wrote in it "Monte Video, November, 1832." The volume treats of the "Changes in the *Organic* World now in Progress." It is true that Lyell had been so far influenced by his friend Cuvier that he commenced the book with a very trenchant criticism of the theory of Lamarck, but he then goes on to discuss a number of problems of extreme interest and importance to the evolutionist—the limits between species and varieties; variation under domestication and in nature; the effects of crossing and the characters of hybrids; the geographical distribution of plants and animals, and the agencies by which it has been brought about; extinction and the appearance of new forms; the struggle for existence; the origin of instincts; and the bearing of all these and similar questions on the interpretation of the geological history of past times. Great as was the influence of the first volume on the mind of Darwin with regard to geological questions, I think no one can now read this second volume without realising that, in respect to biological problems, it must have exercised at least an equally profound effect upon him. It could be easily shown from the "Journal" that all these problems were, from this time forth, ever in Darwin's thoughts, and as new observations were made by him, he delighted to think, as shown by his letters, that they would "interest Mr. Lyell," who was at that time not personally known to him.

I am very far from suggesting that the collection of the fossil bones at Punta Alta and the perusal of Lyell's second volume made Darwin an evolutionist. On the contrary, I fully admit, with Dr. Francis Darwin, that it was the series of wonderful relations revealed to him towards the end of the voyage, by his study of the faunas of the Galapagos Islands, that had the preponderating influence in moulding Darwin's views; and I am convinced that anything like a definite formulation of those views did not take place until after his return to England. It was then that, by the re-examination of his collections and the revision of the observations in his notebooks and journal, he was led to bring into close array the various facts and reflections bearing on "the species question," and thus the scattered gleams of light on the subject which he had from time to time caught were first brought to a focus in his mind; nevertheless, it is true that the first of those gleams were those that came to him at Punta Alta and during the perusal of the "Principles."

There is a passage in one of Darwin's letters to Bentham the significance of which, I think, has been somewhat overlooked. Speaking of the fluctuations of opinion on the question of the immutability of species, he says:—

"I, for one, can conscientiously declare that I never feel surprised at anyone sticking to the belief of immutability. . . . I remember too well my endless oscillations of doubt and difficulty. It is to me really laughable, when I think of the years which elapsed before I saw what I believe to be the explanation of some parts of the case; I believe it was fifteen years after I began before I saw the meaning and cause of the divergence of the descendants of any one pair."[29]

Fifteen years after 1832 would bring us to 1847, a period at which Darwin was fully immersed in the task of "making and unmaking species" among the Cirripedes, and in their classification; and it may well have been the consideration of "one pair" of these that led him first clearly to realise "the meaning and cause of divergence." In his autobiography he wrote, "Long after I had come to Down" (which was in 1842) "whilst in my carriage to my joy the solution occurred to me," and "I can remember the very spot in the road."[30] Although, as Dr. Francis Darwin has shown,[31] his father had come very near to this idea of divergence when he wrote the 1842 sketch,[32] and the same is true with regard to the essay of 1844,[33] it was clearly after these dates that the full significance of the principle revealed itself to his mind, and that it was the result of pondering on questions of classification is shown by his letter of September, 1857, to Asa Gray, which he communicated to the Linnean Society in 1858. He there wrote:—"Each new variety or species when formed will generally take the place of and so exterminate its less well-fitted parent. This I believe to be the origin of the classification or arrangement of all organic beings at all times."[34]

If this reasoning be correct, we obtain the date of a crisis in Darwin's mental development to which he himself attached the greatest importance. However this may be, the letter to Bentham proves what is often overlooked, that Darwin's mind vacillated

for many years before reaching full conviction on the question of evolution. Nor is this surprising; no one can read the suggestive series of letters to Sir Joseph Hooker without realising how great and numerous were the "doubts and difficulties" through which the veteran botanist battled his way towards final acceptance of his friend's views. The publication of the Lyell correspondence showed that the author of the "Principles" at the time of the publication of the first volume was perfectly satisfied as to the truth of organic evolution; this has been insisted upon both by Huxley and Haeckel. Yet, while writing his second volume, Lyell fell so strongly under the influence of Cuvier (whose palæontological work naturally fascinated him) that he not only rejected Lamarck's hypothesis, but at times seemed to hesitate about the evolutionary theory altogether. Again, no one reading Herschel's address to the British Association in 1845, in which the "Vestiges" is so severely handled, could realise the fact that in 1836 he was writing to his friend Lyell that he was satisfied that the principle of continuity was applicable to organic as well as inorganic nature. It is no disparagement to either of these great thinkers to admit that, while weighing carefully the arguments for and against evolution, they inclined sometimes towards one side and at other times to the opposite view, and, in the words of Darwin, underwent "endless oscillations of doubt and difficulty."

JOHN W. JUDD.

ANTHROPOLOGICAL RESEARCH IN NORTHERN AUSTRALIA.

ALL friends of anthropology will rejoice to learn that after an interval of some years Prof. W. Baldwin Spencer, F.R.S., has resumed his researches among the aborigines of Australia. The following particulars as to his work and his plans are extracted from a letter addressed to Mr. J. G. Frazer on September 13.

The Commonwealth Government of Australia is about to undertake measures for the settlement of the Northern Territory, and during the present year it sent a small party to make preliminary investigations in that region. The leadership of the party was entrusted to Prof. Baldwin Spencer. The members of the party went to Port Darwin, and from there across to Melville Island; then they returned to Port Darwin and travelled south about two hundred miles, after which they crossed the continent to the Gulf of Carpentaria. Amongst all the tribes examined by the expedition the belief in the reincarnation of the dead is universal, and the same is true of the notion that sexual intercourse has nothing, of necessity, to do with the procreation of children. "The latter fact," says Prof. Spencer, "is interesting because we now know that this belief exists amongst all the tribes extending from south to north across the centre of Australia." On the other hand, Prof. Spencer found among these northern tribes none of the *intichiuma* or magical ceremonies for the multiplication of the totems which form so important a feature in the totemism of the central tribes; nor could he discover any restrictions observed by the natives in regard to eating their totemic animals and plants. "The absence of *intichiuma* ceremonies," he adds, "is doubtless to be associated with the fact that the tribes in the far north live under conditions very different from those of the central area. They never suffer from drought or lack of food supply. This seems to show that the *intichiuma* ceremonies are a special development of tribes that live in parts such as Central Australia, where the food supply is precarious."

In one or two tribes along the Roper River a very curious totemic system was discovered. Among these people a man must marry a woman of a particular totem, but the children take a totem different from both that of their father and that of their mother. For example, a man of the Rain totem must marry a woman of the Paddy-melon (a species of small kangaroo) totem, and their children are of the Euro (a species of kangaroo) totem. Again, a Porcupine man marries a Lizard woman, and their children are Bats. In these tribes each exogamous class has certain totems associated with it. Again, in these tribes the natives are convinced that the spirit children know into what woman they must enter, so that the offspring shall have the proper totem. Everywhere, too, among the tribes traversed by the expedition, the women and children believe that the sound of the bull-roarer is the voice of a great spirit who comes to take away the boys when they are initiated; but during the initiatory ceremony, when the boys are shown the *churinga* for the first time, they are informed that the noise in question is not made by a spirit, but by the *churinga*, or bull-roarer, which was used in the past by one of the mythical ancestors of the tribe. Lastly, Prof. Spencer could detect among these tribes no trace of anything like a belief in a supreme being. On the whole, he considers that, with minor variations, the beliefs of these northern tribes are closely similar to those of the central tribes.

Prof. Spencer hoped to start about November 1 for another expedition to Melville Island, the inhabitants of which he is particularly anxious to study, as they are hitherto practically uncontaminated by European influence. His intention is to reside among them until February. All anthropologists will look forward with keen interest to the publication of Prof. Spencer's fresh inquiries in this promising region. It is much to be regretted that his former colleague in research, Mr. F. J. Gillen, has been prevented by the state of his health from taking any part in these new investigations.

THE TAAL VOLCANO.

THE latest publication received from the Weather Bureau of the Philippines is entirely devoted to a violent eruption of the Taal Volcano, which took place on January 30 of this year. This volcano, which lies thirty miles south of Manila, is represented by a crater in a small island which rises from the centre of Lake Bombon. As this lake joins Taal in its activities it also must be regarded as an active crater. If its waters could be removed by the deepening of the channel of the river which now drains it, we should have a replica of Mount Aso, in South Japan, viz., a large crater about twelve miles in diameter with an active cone in its centre. The craters of these two mountains rank among the largest of which our world can boast, but they are by no means comparable with the largest in the moon. If, however, the crater plains of Taal and Aso could be lowered to the level on which these mountains grew, they would closely resemble many lunar volcanoes.

The written history of Taal commences in 1572. Since that time the volcano has been fifteen times in eruption, the last being that now under consideration. Often it has obliterated hamlets and villages round the lake, but its last effort has practically cleared out everything. The number of dead is given as 1335, but because so many were buried beneath the ash and mud the exact number will never be determined. Of all the inhabitants round the lake the only survivors appear to have been those who were absent from their

homes. It was exactly the same in 1888, when an innocent grass-covered mountain called Bandai, in Central Japan, blew away its head and shoulders and filled up a valley thirteen miles in length with mud and stones. It buried everything.

Now these calamities are not always such sudden visitations as is popularly supposed. Most, but not all, dogs growl before they bite. Bandai, although it had not erupted for more than a thousand years, gave premonitory signals. From time to time it rumbled and slightly shook. Krakatoa, before it blew three-quarters of an island to the four winds, and opened a red-hot mouth at sea-level to fight two oceans, issued signals of uneasiness. So it was with Taal. On January 27, 1911, it seems to have been the origin of 24 small shocks. Next day the number increased to 197, and on January 29, 113 were counted. What came next we are not told, but at 2 a.m. on January 30, Taal burst forth with terrific energy, and a roar was heard at a distance of 310 miles. A great black cloud crossed with flashes of lightning and illumined with explosions which may have been of electric origin, but in a globular form, rose from the crater from which two or three times a deep red glow appeared.

FIG. 1.—Crater of Taal Volcano before the eruption (seen from the E.S.E.).

FIG. 2.—Crater of Taal Volcano after the eruption (seen from E.S.E.).

Baragraphs at a distance of 242 kms. were greatly disturbed. An analysis of these showed that a depression had travelled at a rate of 112 miles per hour. This depression appears to have been formed by the inrush of air towards the hot volcanic throat. Between twenty-two and thirty-nine miles from this the fall amounted to 2 mm., or 0·8 inch. The inference is that near the mountain the inrush of air must have had a hurricance force and given rise to a real though short-lived tornado. Round the crater everything was "wiped out" or buried in mud. It was not "destruction," but "annihilation." No lava issued. It was Bandaisan over again, a hurricane or whirlwind had levelled houses, torn up trees or stripped them of their leaves and bark. With it all there may have been a *fiery cloud*, like that which issued from Mount Pelée and destroyed St. Pierre. Two days later Father Masò approached the volcano to find it "very peaceful, with puffs of white vapour succeeding each other at intervals of ten to thirty seconds." Nevertheless, as on that day the Observatory in Manila recorded 130 shocks, Father Masò thought "there was still ground for fearing a fresh outburst." The giant was evidently resting after his angry exertions. May he do so for many years, and when he dies the Philippinos will gladly write R.I.P. above his head.

JOHN MILNE.

THE SOLAR PHYSICS OBSERVATORY.

IN April last a departmental committee was appointed to consider and report upon alternative schemes for transferring the Solar Physics Observatory, now at South Kensington, to Fosterdown (Caterham) or to Cambridge. The report of the committee has just been published as a Parliamentary paper (Cd. 5924).

The committee was composed of Sir Thomas L. Heath, Assistant Secretary of the Treasury (chairman), Mr. F. W. Dyson, F.R.S., Astronomer Royal, Dr. R. T. Glazebrook, C.B., F.R.S., director of the National Physical Laboratory, and Prof. Arthur Schuster, F.R.S., chairman of the executive committee of the International Union for Solar Research, with Mr. F. G. Ogilvie, C.B., as secretary. The terms of reference were:—

To consider the alternative schemes for locating the Solar Physics Observatory at Fosterdown and at Cambridge respectively, and to report which of the two schemes is likely to secure the best results for an annual expenditure of approximately the same amount as is now incurred for the work done under the direction of the Solar Physics Committee.

The conclusions and recommendations of three members of the committee, viz. Sir T. L. Heath, Mr. Dyson, and Prof. Schuster, are as follows:—

We are of opinion that, on a balance of considerations, and especially having regard to the advantage to the progress of solar physics which may be expected to accrue from the establishment and support by the University of a real school combining the studies of solar physics and astrophysics, the Cambridge scheme is calculated to give

the better results for an expenditure of approximately the amount now available for the Solar Physics Observatory.

We recommend, therefore, that the solar physics work be transferred to Cambridge, with an initial grant for buildings and a fixed annual inclusive grant-in-aid to the University, provided that the University will agree to the following conditions :—

(1) That the professor of astrophysics be the director of the Solar Observatory.

(2) That there be a committee or syndicate nominated by the University with functions similar to those of the Board of Visitors of the Royal Observatory at Greenwich.

(3) That the Astronomer Royal and the director of the Meteorological Office be *ex officio* members of the committee or syndicate.

(4) That the University undertake to carry out at the new observatory the necessary amount of routine work on the general lines indicated in paragraph 14 (*b*) and (*c*).

(5) That an annual report, to include a statement of the work done, and an abstract of the accounts of the Solar Observatory showing the application of the grant-in-aid, be presented by the director to the committee or syndicate, to be by them transmitted to the Treasury.

With a view to securing the permanence of any arrangement that may now be made, the committee desire to point out the importance of attaching the directorship of the Solar Observatory, if established at Cambridge, to a professorship which is not merely of a temporary character. The University may not be in a position, at present, to give any definite assurance that the professorship will be renewed at the expiration of the present tenure; but we consider it highly desirable that the Government should ascertain, before coming to a final decision, whether the University is willing at an early opportunity to consider favourably the establishment of a professorship of astrophysics on a permanent foundation.

Dr. Glazebrook dissents from these conclusions and recommendations, and remarks :—

I believe that the evidence placed before the committee and the facts detailed in the report lead to the conclusion that, on a balance of all the considerations, a scheme for locating the observatory at Fosterdown, under conditions similar to those outlined in section 23 of the report, could be arranged at an annual cost of 3000*l.* with a capital outlay of 5000*l.*, and would secure the best results.

The report is of a far-reaching character, and if approved will result in the abolition, and not merely in the transfer, of the Solar Physics Observatory, and the dismissal of its staff.

We believe that it has not yet been referred to the Solar Physics Committee, and that steps are being taken to bring disinterested scientific opinion to bear upon the question. So far as public opinion is concerned, *The Morning Post* and *The Daily Graphic* alone have dealt with the matter. The articles are as follows :—

Examination of the majority report of the committee appointed to inquire into the future of the Solar Physics Observatory at South Kensington must awaken surprise and dismay in the minds of those acquainted with the past history and present working of this institution. Founded forty years ago, when South Kensington was almost a vacant site, it was the pioneer in solar observation; the first observatory to examine the solar prominences; the first to observe sunspots systematically, and the first to attempt to correlate solar and terrestrial phenomena. The lead it gave has been followed by other observatories, and the methods it instituted are those which have been adopted by the Mount Wilson Solar Observatory in California, which is now the chief station for observations of the sun.

When the observations at South Kensington were first undertaken, it was understood that the institution was to be regarded as a Government institution, supported by Government contributions. The grant made was not a large one, though to the observatory and its servants it sufficed to make the work done there known all over the world. But it has remained at the insignificant figure of 3000*l.* a year, on the ground that it was useless to spend money for instruments at an observatory which was being so surrounded by high buildings that its opportunities for observation were yearly becoming more limited. That was reasonable, and the observatory, through its officials—as well as through the Solar Physics Committee, which was formed at Sir Norman Lockyer's initiative to coordinate the work of solar observatories—continually urged the removal of the observatory to a more suitable site. Such a site offered itself at Fosterdown, which is a distant fort on the Surrey Hills, 800 feet above the sea, and which became vacant through the abandonment of the obsolete defences of London. The site had the several advantages desirable and necessary in an observatory: it had a very wide sweep of horizon in all directions; it was removed from the glare of electric lights, from smoke, or vibration. Its concrete floors would have been suited in several instances to the requirements of the foundations of the beds of telescopes.

Fosterdown has, however, been rejected by the majority of the committee in favour of Cambridge, on the ground that at Cabmridge there would be closer association with men of science. The loss of efficiency which will result from giving effect to the decision is signal. Cambridge lies in a flat country, and the observatory is in a river valley. The elevation of the observatory there is 70 feet; it is near enough a road to suffer from vibration. Its night observations are prejudiced by the glare of the Cambridge electric lights; its daylight observations by a town's smoke. If it were only on account of the absence of elevation the site of the observatory would be unsatisfactory. Nearly every great observatory in the world has sought elevation. Paris (Meudon) has gone from 194 feet to 534, Potsdam from 112 to 318. Chicago, the Lick Observatory, Mount Wilson, Flagstaff, Nice, Washington, Madras, Mount Etna, are all at an elevation of 1000 feet or more.

Moreover, the committee themselves admit that Fosterdown is the preferable site, a very inadequate expression of the difference between Cambridge and Fosterdown in view of the evidence that was heard. For the Cambridge site is bound to deteriorate as buildings spring up around it and as the traffic on the road increases, causing vibration. Nor is there any proper provision made for the carrying on of the work. The present professorship is not a salaried post, and it is unlikely that a man of high position will be induced to fill the post as Mr. Newall has done, or that he will be attracted by the meagre emolument of 200*l.* offered in connection with the new post. The committee has apparently neglected the view that the true work of a university is to train and fit men to undertake work. For this Cambridge is already adequately equipped, and this is the legitimate work of a professor rather than the management of an important scientific institution for the conduct of research. As regards Fosterdown, the committee admit that it is probably as good a site as can be found in England.

Nor can the report of the committee be accepted with confidence. From the scientific standpoint the opinion of the Treasury representative can naturally carry no weight. The three other signatories of the report are all men of the highest standing, but they are all old Cambridge men, and without their being in any way conscious of bias, it is not improbable that they may have been unconsciously influenced in their view by their natural loyalty to Alma Mater. Even so, Dr. Glazebrook, who, as president of the National Physics Laboratory, has especial experience in the work of administration, has dissented from his colleagues, advocating the establishment of the observatory at Fosterdown, and recommending that it should be under a director who should give his whole time to the work.

Lastly, quite apart from the material disadvantages of the Cambridge site, there is the far more important one that the removal thither, which would make the Solar Physics Observatory an appanage of an observatory already existing, would imply the dissolution of an institution and the dispersal of a staff which is of international importance and repute.—*The Morning Post.*

In astronomical circles the recommendation of the departmental committee that the old Solar Physics Observatory at South Kensington should be removed to Cambridge has been received with surprise. Economy is the one practical reason for the recommendation; in the words of a well-known astronomer to a representative of

The Daily Graphic, "the choice of Cambridge seems to be because it is cheap."

All the great observatories of the world are moving upwards.

The Paris Observatory at Meudon has removed from 194 feet to 534 feet.

Sicily (Mount Etna), 155 feet to 9735 feet.

Berlin (Potsdam), 112 feet to 318 feet.

Madras (Kodaikánal), 23 feet to 7745 feet.

Vienna, 787 feet to a neighbouring mountain.

Washington (Mount Vernon), 200 feet to 1725 feet.

Chicago Observatory is 1105 feet, the Lick Observatory 4209 feet, Mount Wilson 5712 feet, Flagstaff 7293 feet, Nice 1240 feet.

It has become imperative, in the interests of the accuracy which modern astronomical observation demands, to take the observations well above ground, mist, and fog; and to remove them to sites as distant as possible from the smoke of towns by day and the glare of their lights by night; and their vibration at all times. Not one of these advantages will be derived from the suggested site which the new Solar Physics Observatory would occupy at Cambridge, which lies in a river valley. The observatory would be near a road; there is the smoke of the town, not to speak of the cement works at Cherry Hinton; and there is the glare of the town's electric lights at night. This is easily perceptible five miles away at Little Shelford. Moreover, the height at which the observatory will be stationed is only 70 feet above sea-level. That is perhaps better than the present site at South Kensington, which is only 27 feet above river-level, but not much. The site which was suggested by the Solar Physics Committee was Fosterdown, near Box Hill, in Surrey. That is 800 feet above the sea, and is one of the best sites for astronomical purposes in England. It has wide horizons, no lights near, no traffic, no smoke. Nor is it very dear. The land is Government land, being part of the ground lately occupied by one of the obsolete forts for the defence of London.

More serious, or at least as serious as the rejection of the Fosterdown site in favour of one at Cambridge, is the proposed dissolution of the integrity of the old Solar Physics Observatory, which will henceforward become a mere branch of Cambridge Observatory. It is a very poor reward for services and work done lasting over a generation. The pioneer observation of the South Kensington Observatory is known all over the world, and has been a model for other observatories to follow. One cannot believe that the astronomical world will hear of its dissolution without disappointment and indignation.—*The Daily Graphic.*

NOTES.

REPLYING to Mr. Sandys in the House of Commons on Monday last, Colonel Seely made an important announcement on the subject of military aviation. He stated that the War Office has a progressive policy in the matter, and has hitherto only hung back because it wants to be quite sure, in buying a great number of machines, that they are of the most useful type. The Service now possesses sixteen aëroplanes of eleven different types, of which seven are biplanes and four monoplanes. It is proposed to pay officers who obtain the Aero Club certificate a sum of 75*l.* towards their expenses, and such officers will be attached to the Army Aëroplane Battalion for a course of special instruction, which will include navigation and map-reading. They will then be expected to pass for a certificate similar to the French superior military certificate. The intention is, finally, to provide an efficient service of aërial scouts both for the Navy and for the Army. One hundred officers will be trained immediately as pilots and observers, and non-commissioned officers and other ranks will also be trained. In the discussion that followed, Mr. R. Gwynne asked whether the War Office intends to subsidise experiments, but no answer was given. As comment on the foregoing, it may be interesting to enumerate what machines the Government actually possesses. They are as follows:—*Biplanes:* one original Wright, presented by the late Hon. C. S. Rolls (never flown, and now dismantled); one Howard Wright, purchased from Captain Maitland (broken up); one Paulhan (broken up, capable of repair); one de Havilland (worn out, must be entirely rebuilt); one experimental Voisin Canard type (broken up); one Farman (out of date); one Bréguet; and several Bristols. *Monoplanes:* four Valkyries, presented by Mr. Barber (one broken and two without motors, leaving one effective); one Nieuport; and one Blériot (formerly the property of the late Lieut. Cammell). With regard to the French superior military certificate, the rules for this were issued by General Roques last June, and lay down that military aëroplane pilots must possess the Aero Club (F.A.I.) certificate and the military aviator's certificate. The latter is granted to officers, non-commissioned officers, and men of the regular or of the reserve and territorial army who, possessing the Aero Club certificate, have passed a series of tests to be determined each year in accordance with aëronautical progress. For the present year candidates must have accomplished three closed circuits at a height of at least 300 metres, each circuit comprising a cross-country flight of 50 metres, the landing being made at the starting place. The aëroplane must be of a military type, and carry an overload. Candidates have also to pass an examination on aëroplane motors.

THE notices of aviation feats and fatalities which appear in the daily Press do not often afford the scientific inquirer much indication of any advances in our knowledge of the principles of mechanical flight. The remarkable glide which Mr. Orville Wright performed on October 24 reminds us that there is still much to be done with gliders, and that flight as a sport does not necessitate a costly motor-driven aëroplane. The glide in question, which lasted about ten minutes, was performed at "Kill Devil Hill" in a wind blowing at about fifty miles an hour. By careful manœuvring Mr. Wright caused the wind to pick him up from the top of a sand dune, and in successive gusts he rose 150 feet, finally gliding to the ground. Mr. Wright stated that he had proved that a man can remain in the air without a motor provided there is sufficient wind. The question which naturally suggests itself is how far this feat was due to upward currents caused by the wind blowing up the sides of the dunes. It is one thing to hover round a hill top under such conditions, but it would be a very different task to make use of Langley's "Internal Work of the Wind" in a flight across a bare plain or over the sea.

IN the House of Commons on Monday, October 30, the Home Secretary was asked whether his attention had been directed to the views expressed by Sir William Ramsay in his presidential address to the British Association concerning the exhaustion of the coalfields of this country, and whether the Government anticipated taking any steps tending to the conservation and lessened waste and export of this source of energy supply, having regard to the extent to which the nation's commercial position and the support of the industrial population were dependent on it. In the course of his reply, Mr. McKenna said:—The president's forecast of the probable duration of the coal supplies of the country does not take into consideration certain factors which have an important bearing on the question. In the first place, the estimate took no account of the large amount of coal in fields unproved at the time of the inquiry of the Royal Commission, nor of the amount of coal lying below the depth of 4000 feet which the commission took to be the present limit of workable coal, but which it may be

found possible hereafter to exceed. These two sources the commission estimated at more than 39,000 million and 5000 million tons respectively, or together nearly half as much as the amount of coal estimated to exist in the proved coalfields. In the second place, the estimate was based on the assumption that the output of coal would continue, at any rate for some time, to increase at the same rate as in the past. The commission, on the other hand, considered that at a time not far distant the rate of increase of output would become slower, to be followed by a period of stationary output, and then a gradual decline. The suggestion which Sir William Ramsay is reported to have made, that Parliament should impose a penalty on wasteful expenditure of energy supplies, would involve an amount of control over the industries of the country which, under present conditions, it would be impossible for any Government to undertake. The commission looked forward to the introduction of considerable economies in the future; and I am advised that both in the working and in the using of coal progress is being made in this direction.

M. HENRI MARTIN presented to the Paris Academy of Sciences on October 16 a note on the skeleton of Neanderthal man discovered by him at Quina, in the department of Charente, during September last. This is the fourth find of Neanderthal man which has been made in the south-west of France during the last four years. Former discoveries were made in the valley of the Dordogne, or of its tributary the Vézère, while the present has been made in the valley of a tributary of the Charente, fifty miles further to the north. The stratum of sandy clay in which the skeleton was found is regarded by M. Martin as a former bed of the adjacent stream, and as corresponding in date to the lower strata of the Middle Quaternary deposits. In former discoveries of this nature there was evidence that the remains had been buried or been naturally entombed, but in the present case the evidence points to the remains having been embedded during the formation of the deposit in which it was found. In the same stratum were found flint and bone implements, which M. Martin ascribes to the older Mousterian civilisation. The teeth are very similar in character to those found recently in a cave in Jersey, and described in the current issue of *The Journal of Anatomy and Physiology* by Messrs. Keith and Knowles. The skull, which has become broken along the sutural lines, is said to show the well-known characters of the Neanderthal race in a very pronounced degree. The remains of the skeleton have been transported to Paris still embedded in the blocks of loam in which they were discovered, and will ultimately be added to the collection in the Muséum d'Histoire naturelle.

AGRICULTURISTS will regret to learn that M. Gaston Gautier recently died at Narbonne, at seventy years of age. M. Gautier, who was brother of M. Armand Gautier, president of the Academy of Sciences, was a member of the Société de botanique de France, and had published several botanical memoirs. But his great claim to fame is that he introduced the culture of the vine into a region that had been little better than a huge pestilential swamp round Narbonne. The first efforts at reclamation were made on his own estate of Craboules, and finally met with such success that many of his neighbours followed his example; by degrees the swamp gave way to fruitful vineyards.

THE death is announced, at ninety years of age, of Mr. John C. Fuller, whose name is familiar to electricians in connection with the Fuller bichromate battery. A correspondent of *The Times* points out that Mr. Fuller was at one time an assistant of Faraday. He joined the Electrical and International Telegraph Company in 1854, and during his connection with it worked with Latimer Clark and Sir William Preece. One of the results of Mr. Fuller's early studies was the invention of the universal battery system, by which one set of cells works a whole group of circuits. He invented several other forms of battery. About 1857 he assisted Messrs. Silver and Co. (the founders of the India-rubber, Guttapercha, and Telegraph Works Company) in applying indiarubber to telegraph purposes. Here he designed the machines and methods for covering wire and made vulcanite insulators. Later, before founding his own firm, Messrs. John C. Fuller and Son, he assisted Mr. W. T. Henley, the submarine cable manufacturer. At this time he invented and patented the mercury bichromate battery.

IT is with deep regret that we learn of the premature death, at fifty-four years of age, of Prof. Alfred Binet. Prof. Binet was director of the laboratory of physiological psychology at the Sorbonne, and was very well known among psychologists—above all as an ardent investigator of the first rank into problems of child psychology. He founded "L'Année Psychologique" in 1897, in which appeared, year by year, highly important articles from his own pen. Among many well-known books of his upon psychological topics may be especially mentioned "L'Étude Expérimentale de l'Intelligence," "La Suggestibilité," "L'Âme et le Corps," and "Les Idées modernes sur les Enfants" (his latest publication). The science of psychology has suffered a severe loss in his death.

THE annual Huxley memorial lecture of the Royal Anthropological Institute will be delivered on Thursday, November 23, in the theatre of the Civil Service Commission, Burlington Gardens, S.W., by Prof. F. von Luschan, whose address will be on "The Early Inhabitants of Western Asia." Mr. Alfred P. Maudslay, president of the institute, will occupy the chair.

THE council of the Institution of Civil Engineers has made the following awards in respect of papers published in Section ii. of the Proceedings for the session 1910–11:—Telford premiums to Messrs. S. M. Dixon, H. J. F. Gourley, J. Holden, A. Rogers, A. E. Griffin, Dr. F. C. Lea; and a Crampton prize to Prof. W. E. Dalby. The Indian premium for 1911 has been awarded to Mr. C. E. Capito, and the Webb prize to Mr. F. W. Bach.

THE list of lectures to be given on Mondays and Thursdays during the present session at the London Institution, Finsbury Circus, London, E.C., has been circulated. Among the numerous subjects of interest to be dealt with in the lectures we notice the origin of life question, by Dr. H. C. Bastian, F.R.S.; life on the high mountains of Mexico, by Dr. H. F. Gadow, F.R.S.; man under the microscope, by Dr. Alex. Hill; storm rains, by Dr. H. R. Mill; alchemy, by Mr. M. M. Pattison Muir; and waves of the sea, by Dr. Vaughan Cornish.

AT the meeting of the London Section of the Society of Chemical Industry, to be held on Monday, November 6, at Burlington House, Dr. E. G. Acheson, of New York, will read a paper on deflocculation as affecting lubrication. Dr. Acheson is well known as the inventor of lubricants consisting of deflocculated graphite—"Aquadag" and "Oildag" of carborundum, &c. The paper should be of interest to all who are concerned with lubrication and lubricants. Dr. Acheson will also give an address to the Faraday Society on Wednesday, November 8. Non-members of the society will be admitted by ticket, to be

obtained upon application to the Secretary, 82 Victoria Street, S.W.

The council of the Royal Institute of Public Health has accepted an invitation from the Chief Burgomaster of Berlin to hold the congress next year in that city on July 25–28. The congress will include the following sections and presidents:—State medicine, Sir T. Clifford Allbutt, K.C.B., F.R.S.; bacteriology and comparative pathology, Prof. G. Sims Woodhead; child study and school hygiene, Sir James Crichton-Browne, F.R.S.; military, colonial, and naval, Major Sir Ronald Ross, K.C.B., F.R.S.; and municipal engineering, architecture, and town planning, Mr. P. C. Cowan. Facilities will be afforded for visiting the various public health and educational institutions in Berlin in connection with the Imperial Board of Health, the Municipality, and the University.

In connection with the 200th anniversary of the foundation of the Spalding Gentlemen's Society, in 1709, the society has recently built a home for its library and museum, which also includes a magnificent lecture theatre, committee rooms, &c. The new building was opened on October 25 by Sir Henry H. Howorth, K.C.I.E., F.R.S., who referred to the extraordinary fact that a society should have carried on its work for two centuries and should then be in a position to purchase a building for its treasures. In the evening there was a public lecture on "The Romans in Lincolnshire," by Mr. T. Sheppard, in which he described many thousand relics of the Roman period, now in the museum at Hull, from a little-known site on the north Lincolnshire coast. Sir Harry Howorth occupied the chair. During the day Mr. Sheppard also gave an address on the use and value of local museums.

In *The Quarterly Review* for October M. Salomon Reinach reviews the present condition and progress of mythological study. He shows how the earlier explanations of myths suggested by writers like Fontenelle, De Brosses, David Hume, and Dupuis gave way before the researches of Grimm and Mannhardt, to be succeeded by the theories of Kuhn and Max Müller. These last, in their turn, were superseded by the anthropological school, under the leadership of "that wittiest of scholars and most scholarly of wits," Mr. Andrew Lang. This revolt against the philologists was largely due to the advance in the knowledge of philology, which no longer accepts the identifications of the names of many Greek and Roman deities with those of India advanced by Max Müller himself and extended by his more ardent followers, like De Gubernatis and Sir G. Cox. It was also the result of the colonial policy of England which tended to extend the horizon of research from Aryan gods to the mythologies of savage races. The methods of the anthropological school were still further extended by W. Robertson Smith and J. G. Frazer. But the views of these last authorities are already disputed by the psychologists and sociologists. M. Reinach closes his instructive survey of the situation by the remark that "underlying and stimulating the work of criticism, as applied to the chief results of the anthropological school, I see, at all events in my own country, the ever-active upholders of tradition and established creeds."

At a meeting held in Norwich on October 26, 1908, a society was established for the study of prehistoric archæology, especially with reference to the eastern counties, and shortly afterwards it adopted the title of "The Prehistoric Society of East Anglia." We have lately received the first part of its Proceedings, an octavo of 121 pages, containing a report of the work of the first two sessions, with several original papers printed in full. In a communication on the flint implements of sub-crag man, Mr. J. Reid Moir describes his well-known discovery of flints, reputed to have been worked by man, in deposits that, in some cases, are admitted by distinguished geologists to be undisturbed Red Crag. Dr. W. Allen Sturge, M.V.O., the first president of the society, contributes not only an appropriate inaugural address, but also a rather voluminous paper on the chronology of the Stone age. Although the views expressed in this paper are based to a large extent on the study of his extensive collection at Icklingham Hall, in Suffolk, as well as on local field-work, they are likely to evoke no little opposition, both from the geological and the archæological sides. The superficial scratches on many worked flints of Neolithic age he refers to glacial action, and thence concludes that an ice period, with several phases, must have occurred in Britain since the incoming of Neolithic man. Similar evidence in the case of certain palæoliths is accepted as proof of at least one Glacial period during Palæolithic times. Dr. Sturge ventures to suggest that the Neolithic age may have begun about 300,000 years ago, and the Palæolithic perhaps a million years ago. In forming these startling conclusions, he relies on Croll's hypothesis, which, although abandoned by most geologists, he does not admit to have been yet disproved.

Naturen for October contains an article by Prof. A. W. Brogger on prehistoric stone implements, the rock-shelters where some of them were found, and the remains of mammals and birds by which they were accompanied.

According to the report of the New Zealand Scenery Preservation Board for 1910–11, a total of 25,442 acres was reserved during the year under review, this bringing up the total of the reserved areas to 65,989 acres. It is pointed out "that by virtue of past legislation all scenic reserves and national parks in New Zealand are practically sanctuaries for the native birds and game, and no shooting or killing whatever is permitted on them. The greatest care is taken to keep them free from noxious weeds, and wherever practicable and advisable the fencing of the external boundaries has been proceeded with, particularly when the reserve adjoins settled land or a road in general use."

In *Himmel und Erde* for October (Jahrg. 24, Heft 1) M. Ficker contributes the first of a series of popular articles on the bacteria as the friends and foes of man. After a brief historical introduction, the classification and structure of the bacteria are considered, with illustrative figures.

A Bulletin (No. 146) has been issued by the Agricultural Experiment Station of the Rhode Island State College, U.S.A., on the cholera-like diseases occurring among poultry. It is shown that, in addition to the well-known micro-organism of chicken cholera, first studied by Pasteur and Toussaint, several other microbes cause similar diseases among poultry, some of which possess extreme power of infecting.

Botanists engaged in systematic work, or interested therein, will find in the catalogue No. 22, "Botanica Geographica," issued by Messrs. Dulau and Co., Soho Square, London, an extensive assortment of second-hand literature offered for sale. The items are most numerous under the sections devoted to Europe and North America; contributions to the botany of Africa are also well represented.

A second contribution to their studies of Indian fibre plants, prepared conjointly by Mr. and Mrs. A. Howard,

deals with *Hibiscus cannabinus*, popularly known as Deccan or ambari hemp, and *H. Sabdariffa*, the Rozelle plant; it is published in the Memoirs of the Department of Agriculture in India as vol. iv., No. 2, of the botanical series. The investigation was primarily directed towards analysing the ordinary crops with the view of eliminating cross-fertilisation and securing uniformity of product. Five varieties, showing differences in the seedling and early vegetative stages, were isolated; descriptions of these and coloured figures are supplied. Two of the types are regarded as specially promising, and it is intended to develop these by pure-line cultures. The account of *H. Sabdariffa* is confined to comparative notes on pollination and the descriptions of four varieties.

THE interesting chapter on the history of fossil botany, chosen by Dr. D. H. Scott as the subject of his presidential address to the Linnean Society at the close of the last session, dates back three-quarters of a century, to a time when Witham in England and Cotta in Germany were prominent investigators, and the more illustrious Brongniart was engaged upon his earlier researches. Morphological elucidation was the guiding principle of Brongniart's studies, and in most cases he found it necessary to discover the required morphological data himself. His "Histoire des Végétaux Fossiles" contains in the introduction a definite recognition of four successive geological periods characterised by different types of vegetation. Witham's chief service was to demonstrate the early prevalence of gymnosperms, and he was also the first to describe the structure of the historic fossil *Lepidodendron Harcourtii*, although it remained for Brongniart to identify the ring of wood. To Cotta credit is due for the foundation of the genus Medullosa, and a virtual recognition of its polystelic character.

IN the *Naturwissenschaftliche Wochenschrift* for October 1 there is an article on the geological study of earthquakes, by Dr. Erwin Scheu, whose name is well known in connection with catalogues published by the International Association at Strassburg. The article deals with macroseisms, or earthquakes which can be felt. The intensities of these should be referred to a scale; but as seismologists are already troubled with sixteen different scales of intensity, it is not clear why Dr. Scheu should add to their number. He, however, suggests one which, he remarks, might be suitable for Europe, but hardly suitable for the tropics. An earthquake which is not felt should, according to the new scale, be indicated by the numeral I, whilst one accompanied by complete destruction, which refers to a megaseism rather than a micro- or macroseism, has an intensity of VII. In a map of isoseists for the earthquake of Jókeö, January, 1906, some of them are, however, marked VIII and IX. In connection with the construction of isoseists, we are told that the intensity of movement exhibited in hard rocks like granite is greater than it is in materials like marl and clay. So far as destructivity is concerned, our impression has been that this is generally the reverse. The influence of fault lines, as, for example, those in the Rhine Valley and mountain ranges, upon the distance to which earthquake motion may be propagated is pointed out. Illustrations are given of the destruction caused to buildings, and the displacements, vertical and otherwise, of land surfaces. Dr. Scheu's article is distinctly popular, and as such suggests phenomena to be observed at the time and after the occurrence of an earthquake.

THE meteorological charts of the North Atlantic and Mediterranean for November, issued by authority of the Meteorological Committee, contain an instructive account of the behaviour of a heavy storm in the North Sea, illustrated by synoptic charts. Between September 28 and 29 a small cyclonic system seems to have formed near 50° N. and 30° W.; on the morning of September 29 the chart for that day shows that the centre was about 57° N. and 25° W., and was advancing towards the coast of Ireland, increasing in velocity and intensity as it travelled eastwards. On the morning of September 30 the centre was near Spurn Head; during the gale an extreme force of 10 (Beaufort scale) was recorded at several stations on the East Coast, and at 6h. p.m. the centre passed over the north of Holland. An interesting point in this storm is that apparently the wind force experienced by vessels in the North Sea was greater than that at many of the land stations in telegraphic communication with the Meteorological Office. The numerous casualties to shipping would also seem to show that the high seas must have been exceptional.

IN *Symons's Meteorological Magazine* for October Mr. W. Sedgwick continues his interesting notes on the weather in the seventeenth century: part iii., autumn (see NATURE, June 1). He points out that at this season of the year such phenomena as heat waves, severe frosts, &c., are not likely to occur, at any rate near London. It is not surprising, therefore, that Evelyn and Pepys made fewer comments than in the case of the other seasons. To those who still firmly believe that the climate of England has changed, the month of October presents special interest, owing to the comparatively high temperatures experienced in that month in recent years. In a paper read before the Royal Meteorological Society on April 19, on variations in English climate, it was shown that for the last fourteen years (1897–1910), except only in 1905, the temperature was above the average in October. So far as can be judged from the chronicles above referred to, this variation in recent years is merely a periodic change, as they do not show that the weather of that month was noticeably colder than at the present time. Frequent references are made to the pleasant weather experienced; only one October (1692) was referred to as a cold month; Pepys described that of 1668 as "the most summer weather that was ever seen." The general character of the weather in November also, as described by Evelyn, was very similar to that of the present time.

IN a paper by Prof. Henry Louis on the mutual developments of metallurgy and engineering, read before the University of Durham Philosophical Society, and published recently in its Proceedings, much interesting information is given about the history of metallurgical processes. It seems to be fully proved that the Assyrians were not only well acquainted with iron, but had attained some considerable skill in its manufacture, having advanced far enough to make chain mail; thus, so far back as 900 B.C., iron manufacture had long passed the rudimentary stages. The only other common metals known to the ancients were lead, copper, and tin, all of which are easily reduced from their ores; brass was known for a very long time before it was discovered that zinc was one of its constituents, it being always made direct from zinc ore; Roman brass coins have been analysed, and found to contain more than 25 per cent. of zinc, so that the material was certainly known to them, although they did not know its true composition. The metallurgy of lead was relatively far advanced; quite a number of pieces of lead of Roman age have been found in this country, the earliest date about 44 A.D., and several of these are marked "EX. ARG.," or desilverised; it is also evident from the composition of articles of Roman lead that the metallurgists of that day

were tolerably well advanced with their methods of desilverisation.

The Electrical Review for October 13 discusses in a leading article the question as to whether there is or is not at the present time a demand for technical men in the electrical engineering profession. After reviewing the evidence afforded by recent letters to the Press, it concludes that the overcrowding of which there have been complaints is confined to the lower branches, and that it is due to the large class of men who have had no technical training. While the general impression that the profession was overcrowded has led to a decrease in the entries of students in the electrical engineering colleges, a decrease which has now gone on for several years, there is to-day, as a matter of fact, a greater demand for technically trained men than the colleges can supply.

IN order to clear up the small differences which still exist in the determinations of the melting points of metals like zinc and cadmium by even the most accurate observers, Drs. Holborn and Henning, of the Reichsanstalt, have compared together a number of platinum thermometers and two constant-volume gas thermometers of Jena glass 59 III., and of quartz glass filled in turn with nitrogen, hydrogen, and helium. Both the Jena and the quartz glass were slightly porous to the helium above 200° C., but the former showed no signs of being permeable to hydrogen up to 450° C. The constant δ of the platinum thermometers lay between 1·486 and 1·510, but in no case did the temperature between 200° and 450° C. determined by the platinum thermometers with the use of the δ formula differ by 0·1° C. from the temperature given by the gas thermometers. The following melting and boiling points were obtained:—tin, 231·8°; cadmium, 320·9°; zinc, 419·4°; naphthalene, 217·96°; benzophenone, 305·89°, on the thermodynamic scale.

FURS which are moth-proof owing to the substitution of indiarubber for animal tissues would seem at first sight to be a fantastic stretch of the imagination only. A curious invention recently recorded, however, would appear to render rubber-backed fur a possible and practical article of the near future. Large skins, or small pelts sewn together, are stretched upon a frame with the fur uppermost in a large flat-bottomed receptacle, which is then filled with water and placed in a freezing chamber. The plate of ice is then removed, and with suitable machinery a thin layer is sawn from the bottom, thus removing the skin, which after thawing is sold for the purposes of leather. The lower surface of the remaining plate is then melted until the fur is slightly exposed, when a coating of rubber solution is applied layer by layer. When the requisite thickness is obtained the rest of the plate containing the fur is melted, and a large seamless pelt, with a sheet of rubber at its base, is the result. Cheapness is one of the many advantages claimed by the inventor. Ladies with valuable furs, which annually cost a considerable sum for cold storage, will wish every success for so ingenious an invention.

SOME interesting observations regarding the formation of hydrocyanic acid during the germination of seeds are contained in a paper by C. Ravenna and M. Zamorani in the *Gazzetta Chimica Italiana* for September 19 (vol. xli., ii., p. 74). The old experiments of Jorissen and the more recent ones of Soave have shown that some seeds, such as sweet almonds and the seeds of *Mespilus japonica*, form considerable quantities of hydrogen cyanide at the beginning of active life. On the other hand, the experiments of Guignard with *Phaseolus lunatus* point to a destruction of hydrocyanic acid at the commencement of germination, especially in the case of etiolated plants. The experiments now described were made on two species of seed, viz. *Sorghum vulgare*, which does not contain appreciable traces of hydrogen cyanide, and a variety of linseed, which contained it in considerable proportion. In the case of the former, hydrogen cyanide was elaborated during germination up to a certain point, beyond which it appeared to undergo progressive destruction; in the latter case a continuous increase of hydrogen cyanide was observed without a point of decomposition being attained. In all cases the rate of production of the cyanide was greater in the green than in the etiolated plants; but on watering the latter with a 2 per cent. solution of glucose during growth, the proportion of hydrogen cyanide formed was increased up to the level of the green plants. The amount of carbohydrates in the seed thus greatly affects the formation of the hydrocyanic acid. The source of the nitrogen remains to be investigated.

THE council of the Institute of Chemistry has inaugurated a series of lectures, the first of which was delivered by Mr. Bertram Blount at King's College on October 26. The chair was taken by Prof. J. Millar Thomson, F.R.S., who said the lectures were an extension of the work of the institute on lines directed to benefit advanced students of chemistry. Except for one or two lectures delivered in its early history, the institute has not assumed in any way the functions of a teaching body, though the charter provides for such functions. Mr. Blount limited his remarks to calcareous cements, and more particularly to the Portland cement industry. Calcareous cements, properly so called, while being plastic, are capable of hardening and are resistant to water. The common fallacy, that the setting of lime mortar is due to the action of lime on the sand with which it is mixed, was once more exploded. Some siliceous materials have an advantage over others as aggregates for mortar. These are known generally as "pozzolanas," and their usefulness depends on the hydrated silica or attackable silicates they contain, which interact with lime and form compounds resistant to the action of water. There seems to be no record that limestones were intelligently chosen for the hydraulic quality of the lime which they furnished until the time of Smeaton, who, in considering with what material he should build the Eddystone Lighthouse, ascertained that Aberthaw limestone was undoubtedly hydraulic. Those limestones which are most hydraulic contain the largest proportion of argillaceous material. This quality may be improved by the addition of what is capable of conferring hydraulic properties on ordinary lime. Mr. Blount also discussed the manufacture of so-called "Roman cement," a crude form of Portland cement made by burning lumps of clayey limestone. Starting with the notion of imitating Roman cement, the progenitors of the Portland cement industry arrived at the idea that when chalk and clay were mixed and burned an hydraulic material was produced which, when ground, would set and form a strong, sound cement.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR NOVEMBER:—

Nov. 6. 3h. 37m. Moon eclipsed, partly visible at Greenwich.
,, 12h. 11m. Saturn in conjunction with the Moon (Saturn 4° 18′ S.).
7. 7h. 19m. Mercury in conjunction with Jupiter (Mercury 1° 50′ S.).
,, 20h. 50m. Mars in conjunction with the Moon (Mars 2° 53′ S.).
9. 18h. 0m. Saturn at opposition to the Sun.
10. 21h. 31m. Neptune in conjunction with the Moon (Neptune 5° 52′ S.).

11. 13h. 0m. Ceres in conjunction with the Moon (Ceres 0° 48′ S.).
16. 6h. 58m. Venus in conjunction with the Moon (Venus 1° 13′ S.).
18. 4h. 0m. Jupiter in conjunction with the Sun.
21. 20h. 24m. Mercury in conjunction with the Moon (Mercury 1° 28′ N.).
24. 17h. 0m. Mars at opposition to the Sun.
25. 5h. 41m. Uranus in conjunction with the Moon (Uranus 4° 44′ N.).
,, 20h. 0m. Venus at greatest elongation W. of the Sun.

OBSERVATIONS OF COMETS.—It appears from a note by Mr. Knox Shaw, in No. 4531 of the *Astronomische Nachrichten*, that the discovery of Borrelly's comet, 1911*e* (1905 II.), was made with the Reynolds reflector, but was a visual observation, photographs being secured later; the comet's magnitude on September 19 was 13·0 to 13·5, and there was no marked nucleus.

Messrs. Innes and Wood describe the Johannesburg observations of comets 1911*b* (Kiess) and 1911*d* (Encke) during August and September, and Mr. Innes compares the reduced places of Encke's comet with the positions given in Dr. Backlund's ephemeris. The smoothed O–C difference in R.A. increases from 28·3s. on September 3 to +47·3s. on September 14, the corresponding figures for declination being −4·7′ and −6·2′ respectively. The magnitude of the comet early in September was 9·5, and the photographs were taken by Mr. Wood, with the Franklin-Adams star camera, in exceedingly difficult circumstances. Kiess's comet was of about fifth magnitude, and showed no tail on August 17, and then rapidly faded to mag. 11·5 on September 17.

Brooks's Comet (1911*c*), October 27, 4h. 45m. a.m.

Brooks's comet, 1911*c*, has been quite a conspicuous feature of our early morning skies during the past week. A naked-eye observation by Mr. Rolston at Gunnersbury on October 27 showed a straight tail some 15° long, at times seen to extend to 93 Leonis. The head was a little less conspicuous than δ, but brighter than θ, Leonis; thus its magnitude would be about 3·0. As is shown in the accompanying illustration, the comet, at 4h. 45m. a.m., formed a striking triangle with β Leonis and the very brilliant Venus. At 5 a.m. on October 31 a tail some 12° long was seen, and at times a further extension was suspected. The head, seen through opera-glasses of low power, had the appearance of a fairly bright homogeneous disc; to the naked eye it was no less conspicuous than γ Virginis (mag. 2·8).

CHANGES ON MARS.—M. Jarry-Desloges, in a communication to the *Astronomische Nachrichten*, No. 4531, states that there is a bright area on the Mare Tyrrhenum similar to that already noted on Libya, and that the regions of Hesperia and Ausonia are completely modified since October 12. This message is dated October 15 from the new observatory at Sétif, North Africa. In the same journal there is a paragraph stating that observations have been carried on at this station since the end of September; its position is long. = 3° 4′ 21″ E. of Paris, lat. = 36° 11′ 19″ N., and it is situated at 1113 m. (3650 feet). At such an altitude the air is quite clear and suitable for astronomical observations, and M. Jarry-Desloges hopes to be permitted to confirm observations of the Martian surface made at other observatories. To this end he asks for early and brief communication of the detection of any remarkable phenomena; the address for letters is: Astronome de Service à l'Observatoire Jarry-Desloges, Sétif, Algeria; and for telegrams: Observatoire Sétif, Algeria.

COLOUR PHOTOGRAPHS OF SATURN.—Having secured the colour photographs of Mars recently described in these columns (October 19), M. Tikhoff turned his attention to a similar study of Saturn. It had been remarked, some years ago, by M. Belopolsky that the spectrum of the rings of Saturn appeared to extend further into the ultra-violet than did the spectrum of the disc, and this suggested the use of colour screens. With screens prepared by M. Tikhoff, M. Belopolsky therefore employed the 30-inch refractor in 1909 and during the earlier months of the present year to secure colour photographs of the planet. Two parts of the spectrum were used, the "indigo-violet" (390–450 $\mu\mu$) and the "yellow-green" (495–620 $\mu\mu$). M. Tikhoff examined the plates, and arrived at the following general conclusions. Passing from red to violet, the difference in intensity of the edges and centre of the ball diminishes, and finally disappears; the equatorial band is most brilliant in the red and darkest in the violet. The behaviour of the rings is directly opposite to that of the ball, but the edges of the disc and the contiguous parts of the rings are equally intense in all radiations. Observations of the spectra of the various parts confirm these conclusions, which may be explained by the presence of an atmosphere about the disc and none about the rings. It would also appear, from their similarity of transmission, that the particles forming the rings and those forming the atmosphere about the disc are of similar magnitude; that is to say, the pulverulent particles of which the rings are built up have diameters which, in the mean, are less than wave-lengths of light.

AURORÆ IN MIDDLE LATITUDES.—Referring to Sir Lauder Brunton's letter describing a pseudo-aurora seen at St. Beatenburg, Switzerland, Dr. Krebs sends us a card saying that he too saw flashes of light in the north, as seen from Grossflotbek, at 9h. 10m. (G.M.T.) on August 21. The sky was then nearly three-parts covered with cloud, and thunderstorms prevailed about that period. As a possible explanation of the phenomenon he refers us to an article by himself in *Urania*, No. 9 (February 26, 1910), where he describes a light which he saw off Nantucket on May 15, 1909, which was seen from Blue Hill at a corresponding time. As seen by him it was in the N.E.–N.W. region, but seen from Blue Hill it was south of the E.–W. line; thus it lay between the two stations, between lat. 40·5 N. and 42° N. Perturbations of the compass accompanied the apparition, and it is suggested that a charged cloud capable of giving these and emitting the flashes of light passed somewhere between the two stations.

THE MINOR PLANET 1911 M.T.—Dr. Palisa's description of how he found the new and important minor planet 1911 M.T. is given in No. 4530 of the *Astronomische Nachrichten*. He first drew it on his chart on September 29, but found its position empty on October 3. When seen on this date the object appeared to present a nebulous appearance, suggesting the possibility of its being a comet, but a further observation on October 4 negatived this.

GEOLOGICAL WORK IN THE UNITED STATES.

THE papers dealt with under this heading are merely representative of a large amount of literature devoted to the understanding of the ground on which the United States have become founded. Whether from an educational or from a more economic point of view, this wide territory continues to be actively explored, and the existence of State surveys, side by side with that centred in Washington, testifies to the value set upon geological research. The thirtieth and thirty-first annual reports of the U.S. Geological Survey, issued by the director, G. Otis Smith, in 1909 and 1910, show how the survey has often preceded its topographers in the field. These reports now indicate the main features of administration and publication during a fiscal year, the scientific papers being wisely issued in a separate form. J. M. Nickles supplies bibliographies of North American geology for 1908 and 1909 (Bulletins 409 and 444), with useful subject-indexes.

As a sample of the present convenient form in which the Geologic Atlas is obtainable, we may mention folio 169, the Watkins Glen-Catatonk Folio, by H. S. Williams, R. S. Tarr, and E. M. Kindle. In the "field edition," with its low price of 25 cents, the maps are folded into a pocket in the octavio memoir, which supplies an illustrated description of the district, occupying 242 pages. Two topographic contoured maps are given, and are followed by two showing "areal geology" and two showing "surficial geology," printed in colours over the topographic groundwork. The district, lying in the Allegheny Plateau, between Lake Ontario and the Pennsylvanian border, furnishes R. S. Tarr with a good field for glacial investigation. He traces two epochs of ice-advance, the first being especially accompanied by overdeepening of the valleys.

S. R. Capps describes, in Bulletin 386, the "Pleistocene Geology of the Leadville Quadrangle, Colorado." Here, again, considerable overdeepening and widening of valleys has occurred (p. 12), and the country includes typical topographic features due to glacial erosion and deposition (Fig. 1). W. M. Davis has already examined some of these, and his influence may be felt in the explanatory passages with which the present memoir introduces us to the district. The bulletin is eminently one for scientific students who may travel in central Colorado. W. R. Calvert describes (Bulletin 390) the Lower Cretaceous coal-bearing strata of Lewistown, Montana, in a district where Carboniferous and Jurassic beds are also represented. P. S. Smith (Bulletin 433), in the Seward Peninsula of Alaska, has encountered (p. 97) the phenomena of soil-cap movement that have been somewhat grandiloquently styled "solifluction" by Swedish authors. He describes independently how the frozen earth receives a burden of detritus, and how this burden flows downhill when the ice below it begins to melt. Materials from various levels of the hills thus become mixed, to the annoyance of the prospector, who seeks his gold in the stream gravels that are liable to be covered by an "earth run." Vegetation flourishes in places on soils laid down, by streams or by earth-sliding, on beds of ice, which originated in ancient snowfalls. The maps in this bulletin show well the auriferous gravels, and the uplifted coastal plain on Norton Sound. In Bulletin 435, N. H. Darton records "a reconnaissance of parts of north-western New Mexico and northern Arizona," and illustrates once more the famous cañon country. The problem of the sandstone crater of Coon Butte (p. 72), which is 3900 feet in diameter and 600 feet deep, is believed to be best met on the volcanic hypothesis of a steam-explosion.

N. H. Darton has also studied the geology and water resources of the Black Hills region in S. Dakota and Wyoming (Professional Paper 65), in continuation of his report of 1901. This district includes, among other bold buttes left by erosion on the plateaus, the remarkable columnar mass known as the Devil's Tower (Fig. 2), which the author believes to be connected with an underlying vent. The nature of the "igneous rock" is not stated.

Professional Paper 72, by L. C. Glenn, on "Denudation and Erosion in the Southern Appalachian Region," includes a useful essay on erosion for the non-geological reader, with illustrations from areas under vegetation and those from which grass and forests have disappeared. The disastrous effects of sulphuric acid fumes from smelting furnaces are shown in views near Ducktown, Tennessee (Plate xvii.). The paper is thus of interest for geographers, and includes photographs of stream-meanders and river-flood phenomena.

Palæontology is represented by several bulletins. E. M. Kindle (No. 391) treats of the Devonian fauna of the Ouray Limestone in Colorado. The upper part of this limestone is marked off by its fossils as Mississippian (L. Carboniferous). Several new species and a new genus of Brachiopods (Syringospira) are described. R. Arnold (No. 396) writes on the "Palæontology of the Coalinga District, California," where strata from the Franciscan (Jurassic?) series up to freshwater Pliocene beds are represented. The eight unconformities indicate the instability of this western region. G. H. Girty describes (No. 436) the fauna of the Phosphate Beds of the Park City formation in Idaho, Wyoming, and Utah, and points out the existence of a specialised type of Carboniferous fauna widely distributed through the west (p. 10). Brachiopods are scarce, and molluscs are unusually common. G. H. Girty has also (No. 439) reported on the "Fauna of the Moorefield Shale of Arkansas," a Mississippian zone which he allies with the Caney Shale of Oklahoma.

FIG. 1.—Spur truncated by glacial erosion, near Crystal Lake, south-west of Leadville, Colorado.

Economic geology is properly dominant in other bulletins. T. N. Dale (No. 404) writes on the granites of Vermont, with illustrations of their utility in the arts. F. L. Ransome, W. H. Emmons, and G. H. Garrey collaborate in a report (No. 407) on the "Geology and Ore Deposits of Bullfrog District, Nevada," an arid region where gold, derived from pyrite, occurs in a series of oxidised ores. Crystalline schists have been developed from Ordovician or

older sediments by pressure and by the intrusion of pegmatite along the planes of foliation (p. 27). Rhyolites form stratified masses on the surface, and contain spherulites (p. 39) up to 4 feet in diameter. These and the desert scenery are well illustrated. Bulletin 417, by F. H. Moffit and A. Knopf, on "The Mineral Resources of the Nabesna-White River District, Alaska," is mainly concerned with the geology, and contains pictures of the piedmont glaciers. Bulletin 420 deals with "The Feldspar Deposits of the United States," and is a practical introduction to the industrial use of pegmatites. T. L. Watson (No. 426) describes, with adequate illustration, the granites of the south-eastern States. The orbicular gabbro-diorite illustrated on p. 145 is proposed for ornamental purposes. The papers on water-resources show, as usual, a close alliance between the work of the Survey and the living interests of the people.

We may mention here a paper issued by the U.S. Department of Agriculture in 1911, by W. H. Waggaman, on the phosphate fields of Florida, in which it is estimated that the deposits of detrital pebbly phosphate, probably of Pliocene age, are "almost inexhaustible." For all that, we may well fear the energy of the modern agriculturist.

FIG. 2.—The Devil's Tower, south of Hulett, Wyoming.

The United States Survey (Bulletin 465) has supplied us with a history of the various Geological Surveys organised by separate States, and we may now mention some recent publications of these bodies. Maryland has issued vols. vii. and viii. of her handsome cloth-bound series. Great attention has been given to road-metal, for roads have now a new meaning in the wealthier States. It is to be regretted that the only way of preserving certain roads in Maryland from the destruction due to uncontrolled motor-traffic is the formation of depressions across them, which check any attempt at furious driving. As in our own islands, legislation is regarded as powerless to remedy the evil. Vol. vii. is concerned with a topographical re-survey of the boundary between Maryland and Pennsylvania, first marked out in 1763.

Wisconsin supports a joint Geological and Natural History Survey, and has recently issued several maps of the lead and zinc mining district, on the large scale of 4 inches to the mile, with contour-lines at intervals of 10 feet.

The annual report of the Iowa Geological Survey for 1909 (received in 1911) contains much matter of interest to the glacialist. The papers written by the geologists, and notably that on Hamilton and Wright counties, by T. H. Macbride, are addressed to any intelligent citizen. They cannot fail to arouse interest in the features that diversify the great flat lands of this central State, nearly four-fifths of which are occupied by prairies. The State is being described county by county, and B. Shimek, in Harrison and Monona counties, illustrates the loess deposits, which often form conspicuous bluffs. Land-shells form the immense majority of the molluscan fossils of these beds, and the author strongly supports (p. 399) the æolian view of their accumulation. The survey of these two counties has led to the discovery (p. 309) of a rich mammalian fauna in the Aftonian interglacial stage, including elephants, horses, and Mylodon. The freshwater molluscs of the same beds are mostly still living in West Lake, Okobozi, Iowa. The botanical report (pp. 426–483) on the prairie flora and its conditions of growth will interest students of plant-distribution. The huge granite boulders of the earlier or Kansan drift, illustrated by M. F. Arey in Plate xi., remind us of those of the North German plain, and the intelligent citizen before mentioned may like to learn more as to how they came into the ice-sheet.

Bulletins 1 and 2 of the Colorado Geological Survey, published in one volume, bound in cloth, describe two mining districts, with the aid of coloured maps.

The Colorado School of Mines issues a "Quarterly," reviewing the mining progress of the State, and geological papers may also be found in the "Studies" published at Boulder by the University of Colorado. J. Henderson writes in the latter (vol. viii., 1910–11, p. 33) on "Extinct and Existing Glaciers of Colorado," with good illustrations and a general introduction to the subject. The glaciers are, of course, interesting on account of their small size and evidences of retreat.

Among papers that have reached us from private sources, we may mention several on Pleistocene features by F. Carney. His inaugural thesis for his doctor's degree at Denison University (Bull. Den. Univ., vol. xiv., p. 335) treats of the glacial phenomena and resulting topography of a part of New York State. The destructive effect of continental ice upon well-bedded and jointed strata beneath is illustrated in Figs. 25 and 26. The same author (*ibid.*, p. 262) has studied the "Raised Beaches" of parts of Ohio, which seem to be glacial lake-terraces rather than raised beaches in the customary sense. They were formed in bodies of water along the frontal margin of the Wisconsin ice-sheet, when it had retreated to the basins of Lake Erie and the other great existing lakes. In accordance with the author's geographic outlook, the terraces are connected by him with the agricultural economics of Ohio. He has also described "Geographic influence in the development of Ohio" in a paper in the *Popular Science Monthly* for November, 1909.

The Grand Cañon of Arizona has attracted D. W. Johnson (Proc. Boston Soc. of Nat. Hist., vol. xxxiv., p. 135) and L. F. Noble (Am. Journ. Sci., vol. xxix., p. 369). The former believes, with W. M. Davis, that the faulting of the district is in the main of ancient date, that is, older than the course of the river. His expedition was chiefly concerned with the examination of this important question. Some modification of Huntington and Goldthwait's report is suggested (p. 157). L. F. Noble's contribution deals with new points in the pre-Cambrian and Palæozoic stratigraphy of the cañon.

C. D. Walcott's progressive Cambrian studies have been referred to more than once in NATURE (see vol. lxxxvii., p. 423). The Smithsonian Miscellaneous Collections have been enriched by them for some years past, and now include (vol. lvii., No. 1) a contribution on the "Abrupt Appearance of the Cambrian Fauna on the North American Continent," presented before the International Geological Congress of 1910. Walcott's view is that life-forms, primarily pelagic, adapted themselves to littoral conditions in Algonkian times, and were first brought over on to the

continental area by the Cambrian marine transgression. Their ancestors are thus to be looked for beneath the existing oceans. The fossils now known from the American Algonkian may have been of fresh or brackish water types; littoral forms were occasionally imported among them from the series continuously developing in the seas. Walcott's studies of the Cambrian faunas of China are continued, with illustrations of new species of trilobites (vol. lvii., No. 4). Evidence is given (*ibid.*, No. 3) that certain medusiform fossils from the Middle Cambrian of British Columbia are in reality holothurians, being characterised by a large spiral alimentary canal. The descriptions and illustrations of these forms possess great interest for all workers among Older Palæozoic strata.

G. A. J. C.

STEREOSCOPIC VISION AND INSTRUMENTS.

WE have received a copy of a brochure entitled "Stereoskopisches Sehen und Messen" (pp. 40, price 1 mark), by Carl Pulfrich. This is the German version, or rather original, of the article "Stereoscope" in the recent new edition of the "Encyclopædia Britannica." A little more detail is given here and there in the German pamphlet than in the "Encyclopædia" article, and the former concludes with a very useful bibliography of papers published in the present century relating to binocular vision, which is not given in the "Encyclopædia." This is to be taken as supplementary to the bibliography in von Rohr's well-known work "Die binokularen Instrumente" (see Supplement to NATURE, March 5, 1908) of memoirs published up to 1900.

The pamphlet gives a concise, but clear and interesting, account of the more important points in the theory of stereoscopic vision; but its main value lies in the brief description which follows of the important modern developments and applications of stereoscopic methods, to which the author has himself so largely contributed. Not the least interesting among these are the well-known stereo-comparator and the so-called "blink" microscope, the latter of which has proved so valuable in the detection of new planets and variable stars. We think it is desirable that attention should be drawn to the very imperfect, not to say unintelligible, translation of Pulfrich's text which constitutes the article in the "Encyclopædia Britannica" above referred to. It is surprising that both translator and editor should have allowed passages to pass which are so far astray from the original. Thus we read: "The reason for this [double images] is that when P (or H′) is *fixed*, the images of H′ (or P) are always separated from one another by the centre of the yellow spot." *Fixed* should be "focussed" (no doubt "fixiert," but the original is here paraphrased). Again: "The power of perception of depth in man is most accurate. *This has been ascertained* by the approximately equal keenness of vision of all normal-sighted people and by the interpupillary distance." This is quite incomprehensible until one learns that the words in italics (ours) are a perversion of "Es wird bestimmt." "Parallax" (Parallaxe) appears as "parallel axis."

It is impossible briefly to convey an idea of the confusion in the mind of the reader caused by numerous errors of this description; but we would strongly recommend all those interested in the subject-matter of the article to refer to Pulfrich's German memoir.

THE TECHNICAL COLLEGE, BRADFORD.

AN important extension of the buildings of the Bradford Technical College was opened by Lord Rotherham on October 25. The extension takes the form of a model experimental mill, in which all processes involved in the production of woollen and worsted cloth, from the raw material to the finished article, can be carried out on a practical scale. The building comprises a three-storey front block 175 feet long, devoted to lecture-rooms, textile testing-room, museum, experimental rooms, &c. Behind this are two large sheds, each 90 feet by 70 feet, one containing the combing, carding, and spinning machinery, and the other the looms. The equipment for the production of yarns of various types is very complete, consisting of Preparing Box, Worsted Carding Engine, Noble Comb, French Comb, French, Cone, and Open Drawing Sets, Flyer, Cap and Ring Spinning Frames. In a separate shed are warping mills and dressing frames, while the power looms include examples of all types. The wool-washing room contains three bowls of a total length of about 80 feet. The practical dyehouse and finishing rooms each have an area of about 300 square yards, and are equipped with full-size machines for the treatment of loose wool, slubbing, yarns, and piece goods.

A detached building houses the power plant, which includes a 30 foot by 8 foot boiler, with superheater, economiser, &c. The engine-house contains four prime movers, a suction gas engine of 125 horse-power, a slow-speed cross-compound engine of 200 horse-power, a high-speed inverted vertical engine of 75 horse-power, and a steam turbine of about the same power. Each of the three engines drives a direct-current generator, while the turbine is coupled to a three-phase alternator. Both engine- and boiler-houses are fitted with a complete set of testing apparatus; but while primarily intended for educational work, the power plant will provide light and electrically transmitted power for three large buildings—the main college block, the extension, and the school of art.

The new buildings have been erected at the cost of about 20,000*l.*, and for the equipment an additional sum of about 14,000*l.* has been provided, which sum would have been much increased but for the generosity of most of the machine makers, who have supplied the equipment on very favourable terms. Much of the machinery throughout the building has been specially designed, so that while of a thoroughly practical character, experimental work not possible in a mill can be carried out.

ZOOLOGY AT THE BRITISH ASSOCIATION.[1]

SECTION D presented a full and varied programme, and the attendance at the several sessions was above the average of recent meetings. This meeting was undoubtedly one of the best of recent years.

As in previous years, there were two lectures of a semi-popular character, which were highly appreciated. Mr. Fred Enock lectured on the "fairy flies" (Mymaridæ), hymenopterous insects of small size and with peculiar delicate wings, without veins, but fringed with long hairs. Mr. Enock, who has devoted many years to the study of this family, illustrated his account by means of a beautiful series of original drawings, shown by the lantern. He described the principal characters of the male and female, and traced the life-history of *Anagrus incarnatus*, the eggs of which are laid in the egg of the frog-hopper.

In his lecture on the fossil reptiles of the Oxford Clay of Peterborough, Dr. C. W. Andrews gave an account of the remarkable assemblage of reptiles occurring in that deposit. The beds in which the remains were found are of Middle Jurassic age, and were probably laid down not far from land and near the mouth of a large river. The horizon at which the remains occur is that characterised by ammonites of the "ornate" group, *Cosmoceras gulielmi* being a common species. Among the remains are those of land reptiles carried down by the river and of many marine forms of several distinct orders. Cetiosaurus, a terrestrial dinosaur allied to Diplodocus, attained a length of 60 feet, the greater part being made up of the greatly elongated neck and tail. Another, but smaller, dinosaur, Stegosaurus, and a pterodactyl, Rhamphorhynchus, were also found. The marine reptiles were more numerous, and of astonishing variety of form; for instance, ichthyosaurs, plesiosaurs of many types, and numerous marine crocodiles of the genera Metriorhynchus and Stenosaurus. The ichthyosaur Ophthalmosaurus was remarkable for the fact that in the adult the teeth were extremely small, and in some cases perhaps absent, so that the food of this animal must have been very different from that of its relatives. In many cases the skeletons were found in a nearly complete condition; in others the carcases seem to have been torn to pieces by predaceous reptiles, the bones being deeply scored by their teeth. Dr. Andrews exhibited a series of lantern-slides showing the actual remains and reconstructions based upon these. He stated that the

[1] "Some Recent Work on Sex" and an account of the discussion on the origin of mammals will form the subject of separate notices.

collection is almost entirely due to Mr. A. N. Leeds, who for the last forty years has closely watched the clay-pits, and has collected most of the specimens, a large series of which is exhibited in the gallery of fossil reptiles in the Natural History Museum at South Kensington.

Momentum in Evolution.

In his opening remarks on this subject Prof. Dendy mentioned that Dr. Smith Woodward, in 1909, had directed attention to the fact that many groups of the animal kingdom, in the course of their evolution, have shown a strongly marked tendency to enormous increase in size, often accompanied by the development of grotesque and apparently useless excrescences. Prof. Dendy instanced as analogous phenomena the extraordinary development of the beak and helmet in the hornbills and of the tusks in the babirusa. In these, and in many other cases which could be adduced, either the entire body or some particular organ appears to have acquired some sort of momentum, by virtue of which it has continued to grow far beyond the limits of utility, although perhaps in some cases a new use may have been found which has assisted the species in maintaining itself in the struggle for existence. An enormous increase in mere bodily size, however, seems in the long run to be always fatal to the race, the place of which will be taken by smaller and more active forms. Prof. Dendy thought there was some ground for believing that a race of animals may acquire a momentum of the kind referred to which may lead ultimately to its destruction, that there is some brake applied to the growth of organs and organisms, but that there are occasions on which the brake may be removed, with results which ultimately prove fatal. He pointed out that the growth of different parts of the animal body is controlled by internal secretions, or hormones, the products of various glands. Disease of the pituitary body leads to acromegaly, one of the symptoms of which is great enlargement of certain parts. Prof. Dendy held that there is good reason for believing that, in the absence of certain specific secretions, the growth of the various organs will continue far beyond the normal limits. He saw no reason why this principle should not be extended to the race, and, paradoxical as it might seem, he thought it possible to explain the growth of the organism as a whole and of its various organs beyond the limits of utility as an indirect result of natural selection.

When a useful organ is first beginning to develop or to take on some new function for which an increase in size will be advantageous, natural selection will favour those individuals in which it grows most rapidly and attains the largest size in the individual lifetime. If growth is normally inhibited by some specific secretion, natural selection will favour those individuals in which the glands which produce this secretion are least developed or least efficient, and, this process being repeated from generation to generation, these glands may ultimately be eliminated, or at any rate cease to produce the particular hormone in question. Moreover, this elimination may take place long before the organ the growth of which is being favoured by natural selection has reached the optimum size. When it has reached this optimum it is certainly desirable that it should grow no larger; but there is no longer any means by which growth can be checked. The inhibiting hormone can no longer be produced; the brake has been taken off, and further growth takes place irrespective of utility, until, when the size of the organ, or it may be of the entire organism, becomes incompatible with the well-being of the individual, natural selection again steps in and eliminates the race. Is it not possible that, the normal checks to growth being thus removed along certain lines by the action of natural selection, a definite direction may be given to the course of evolution which the organism will continue to follow to the bitter end, irrespective of natural selection?

The Food Supply of Aquatic Animals.

Dr. W. J. Dakin directed attention to some of the recent work on the nutrition of marine organisms, first citing the work of Pütter, who showed that there is more organic carbon present in solution in sea water than in the plankton contained in that water. With the view of showing that aquatic animals do use the food in solution, Dr. Dakin adduced the following observations. A specimen of the sponge Suberites, of 60 grams weight, requires as food 22 milligrams of carbon per day, to obtain which the sponge would need to capture 7,400,000,000 *Thalassiosira nana* (or an equivalent of other organisms), and would therefore need to filter several thousand times its own volume of water per hour; but if the food in solution in the sea water be also used, a much more rational quantity of water would suffice to supply the animal's needs. Extraordinarily large numbers of copepods would be required to provide the food of the larger Rhizostomes; but it seems impossible that copepods are captured in such large numbers, for copepod remains are so seldom found in the medusæ. Goldfish living in tap water, without solid food, were able to exist forty-one days; but with soluble organic bodies added to the water the fishes lived seventy-eight days, and the amount of oxygen consumed was found to be in excess of that calculated from the loss in weight of the fish, that is, some oxygen must have been used for the oxidation of substances in addition to those stored in the tissues. Many other facts, *e.g.* that crabs, living in sponges, with only filtered water at their disposal, and that Daphnia can be kept living and growing in solutions containing only dissolved food matter, seem to be in favour of Pütter's theory. Dr. Dakin believed that, though solid food is necessary, food in solution forms part of the normal food supply of aquatic organisms.

Prof. Hartog remarked that there was still much to discover regarding the nutritive apparatus of the lower invertebrates, and that, if Pütter's theory be true, the accessory intestine of some worms and echinoderms, and the rectal pumping apparatus of worms and Crustacea, may serve not only a respiratory, but a nutritive, function. Prof. Herdman suggested that the figures advanced by Pütter were not sufficient either to prove or disprove his contentions, and that renewed investigations are necessary. He also pointed out that copepods, which for a long time were believed not to take solid food, feed on minute diatoms, which, owing to their very small size, had until recently not been observed in the gut of these Crustacea. Prof. Dendy referred to the crabs which live in cavities of sponges, and stated that in most of these cases the crab probably feeds on the sponge, and the latter regenerates as quickly as it is eaten away. Dr. Gemmill stated that one of the difficulties in the way of his accepting Pütter's theory arose from the fact that he was not aware of any soluble organic food material likely to be present in sea water which would not be immediately attacked and broken down by bacteria. Mr. D. J. Scourfield pointed out the great difficulty of estimating the numbers of organisms, and therefore of solid food, present in water, remarking that the rate of increase of smaller organisms, *e.g.* algæ, bacteria, is so enormous that their presence in sufficient numbers in any one catch is not necessary for the explanation of the feeding of the larger organisms, for the small organisms may very soon become so abundant as to provide the necessary amount of food for the larger ones.

The Systematic Position of the Cyclostomes.

Dr. W. W. F. Woodland introduced a discussion on this subject. He described in considerable detail the innervation, musculature, and cartilages (especially the lingual) of the head of cyclostomes, and held that recent work showed that the sub-ocular arch and lingual cartilages could not be regarded as homologous with the palato-pterygo-quadrate bar and glosso-hyal element of gnathostomes. As the musculature of the piston cartilage is innervated by the mandibular nerve, and not by the hypoglossal, modern upholders of the gnathostome ancestry have revived the opinion that the piston cartilage represents the much modified and displaced mandible of gnathostomes, the so-called hyoid representing a quadrate element. Dr. Woodland pointed out that the piston cartilage is not paired, that it does not surround the mouth as mandibular elements should, and held it difficult to believe that it could be a reduced jaw apparatus. The development of the piston musculature and cartilage in the mid-ventral line is inconsistent with the view that they were formerly paired laterally placed mandibular muscles and rami, and the extension of the myotomes laterally in an unbroken series to the extreme end of the head proves that a jaw

apparatus could never have been developed. Dr. Woodland believes, with Balfour, that the branchial skeleton of cyclostomes is not homologous with that of gnathostomes, since, for one reason, in the former the skeleton is developed external to the ventral aorta and the gill vessels, while in the latter it is internal. He concluded that, considering the visceral arches as a whole, it is incredible, if the cyclostomes have originated from a gnathostome stock, that the first two visceral arches should exhibit the differences in development (in time and form) and relationships to nerves and muscles shown by the sub-ocular arch, piston, and styloid cartilages, &c., when compared with the jaw and hyoid arches of gnathostomes.

Prof. Dendy, while agreeing generally with Dr. Woodland's position, pointed out that the lampreys and hags differ markedly from each other. The brain of Petromyzon is primitive, and in Geotria there are two pineal eyes—a very primitive character; the brain of Myxine is highly modified, and pineal organs are wanting. These and other facts suggest that the two subdivisions of the cyclostomes have either had a separate origin or have diverged early from one another.

Mr. E. S. Goodrich held that the absence of jaws in cyclostomes was not proved; the piston apparatus is supplied by the fifth nerve, and this region would therefore seem to be homologous with the mandibular region of the gnathostomes. The gill arches of larval lampreys resemble those of gnathostomes, and though the relations of the branchial basket of lampreys and the gill arches of gnathostomes are not identical ventrally, their relations dorsally are very similar, and therefore the homology of these structures is not disproved. Mr. Goodrich suggested that the piston cartilage of Petromyzon might be homologous with the median cartilages of the branchial apparatus of gnathostomes. He demurred to the suggestion that lampreys and hags have been independently derived from the primitive vertebrate stem, for the two series present certain common characters, *e.g.* the structure of the gills and heart, asymmetry of the vascular system, horny teeth and piston apparatus, hypophysial sac in relation to the nasal organ, which it is unlikely can have been developed independently. He regarded the cyclostomes as monophyletic, and as having diverged very early into two branches, the lampreys and the hags.

Communications on Protozoa.

Prof. Herdman contributed a note on the occurrence of the peridinian *Amphidinium operculatum* at Port Erin. This flagellate organism had not been previously recognised in British waters, and was known only from the coasts of Norway and Belgium. It was first observed at Port Erin early last year, forming brown patches in the troughs of the ripple marks on the beach about half-tide level. The patches varied in size, but were observed for about three weeks. Examination of the sea water in the neighbourhood of the patches showed that the organism was not living in the water; it lived only in the wet sand. The brown patches consisted of an almost pure culture of Amphidinium, the only admixture being a very few examples of a diatom (Navicula). Later in the year brown patches of similar appearance were again observed on the sand, but on examination they were found to consist entirely of Navicula. The Amphidinium had disappeared, but the Navicula had multiplied abundantly. Prof. Herdman cited this as a striking instance of the change in the organisms inhabiting the beach, a change which might readily be, and no doubt had long been, overlooked.

Major C. F. Bishop described his recent examinations of sheep suffering from louping ill, and of ticks which had fed on the sheep. On a film made of blood squeezed from a tick, taken from a sheep which was said to be a typical case of louping ill, he found a single "trypanosome," about 22 μ long, in which the trophonucleus was nearly central and anterior to it the large kinetonucleus. Trypanosomes have not yet been found in any of the sheep examined, but Major Bishop considered it probable that the organism described was connected with the disease in the sheep. He also described other forms which he considered to be blood parasites, and regarded as flagellates, in films of blood from sheep.

A New Hydroid, Epizoic on a New Parasitic Copepod.

Prof. H. F. Jungersen (Copenhagen) described a new hydroid, *Ichthyocodium sarcotretis*, which covers more or less of the exterior of the parasitic copepod *Sarcotretes scopeli*, n.sp., which is deeply sunk into the body of the fish *Scopelus glacialis*. The hydroid consists of polyps, without tentacles, arising from a network of delicate tubes. From the base of the polyps arise medusa-buds which develop into free medusæ (Anthomedusæ). This new hydroid is a corynid, related to *Hydrichthys mirus*, Fewkes, epizoic on the fish *Seriola zonata*. Prof. Jungersen gave a full description of the characters and life-history of the copepod, which belongs to the family Lernæidæ. There is first a "cyclops stage," capable of moving about on the host and attaching itself by means of its strong cheliform antennæ; the pupa stage is passively fixed to the host by means of a hardened secretion from the rostrum. Within the last pupal phase the copulatory form was observed. The latter probably is for a time free-living; after impregnation the female assumes parasitic life anew, but in a more intense form; it pierces the skin of a Scopelus, and, gradually growing, it penetrates the muscles, and finally reaches the intestine. This copepod is found on examples of Scopelus from the eastern part of the Atlantic, and the triple association—hydroid, copepod, fish—seems to be a regular one. The loss of tentacles of the hydroid polyps seems to indicate that the hydroid in some way or other depends on the fish for obtaining its food.

Variation in the Medusa Mœrisia lyonsi.

Mr. C. L. Boulenger gave an account of variations in this Egyptian lacustrine medusa. About 15 per cent. of the individuals examined were abnormal. The abnormal examples fall into two groups: (1) those which deviate from the normal four-rayed symmetry, and (2) those with the normal number of radial canals and primary tentacles, but possessing, in addition, secondary tentacles which are not connected with the stomach by means of radial canals. Some of these multitentacular forms are asymmetrical, and it seems that each quadrant is capable of forming secondary tentacles quite independently of the other quadrants.

The Crop of the Leech.

Prof. Marcus Hartog directed attention to the structure of the septa in the crop of the leech. The crop is divided into chambers separated by distinct simple septa passing inwards from the obvious external constrictions and perforated by a central aperture, circular under ordinary conditions, but vertically elongated in distension. The septum is puckered at the free edge, and contains a circular sphincter, but no divaricator fibres. This structure has probably been so long overlooked because it is inconspicuous in ordinary dissections, and is not easily recognisable in the usual thin transverse sections; it is well seen on examining successive thick slices of a hardened, distended leech.

The Lantern of Aristotle as an Organ of Locomotion.

Dr. J. F. Gemmill gave an account of his observations on the locomotor function of the lantern of Aristotle in the sea-urchins *Echinus esculentus* and *E. miliaris*. The animal progresses, when out of the water, by a series of steps or lurches, more or less well defined, in each of which the urchin is raised on the tips of the teeth as on a powerful central stilt. The steps have a length varying from half an inch downwards, and are repeated at intervals of fifty seconds or less, according to the size of the urchin. There is a rhythmic backward and forward swing of the lantern in the direction of progression. The backward swing is accompanied by powerful protrusion of the tightly closed teeth against the supporting surface, which causes pushing or poling forward of the urchin. The movement is aided by pushing on the part of the spines, and, after a certain stage, by the action of gravity. The forward swing of the lantern is marked by retraction, with opening of the teeth, and serves to bring the latter into position for initiating a new lurch. Experiments on loading, recording surfaces, inversion, equatorial section, rotation, removal of spines, &c., were also briefly noted, and examples of tracks

left by the spines and teeth on a smooth plasticine surface were exhibited with the help of the lantern.

Healthy urchins, moving under water over approximately horizontal surfaces, do not, as a rule, use the lantern for movement, the greater part of their weight being neutralised by the water. There are, however, certain conditions, both normal and experimental, in which the lantern plays an important part in locomotion. Dr. Gemmill brought forward evidence in favour of the view that the locomotor action of the lantern is a particular manifestation of a fundamental rhythmic activity, which can also subserve feeding, boring, respiration, and circulation, and possibly, in addition, the maintenance of turgescence within the ampullæ of the water-vascular system.

Dr. Gemmill also gave a lantern demonstration on the development of the star-fish, *Solaster endeca*.

Echinoderm Hybrids.

Mr. H. M. Fuchs presented observations on the experimental control of dominance in echinoderm hybrids, using *Echinus miliaris* and *E. acutus*. Dr. Shearer and Mr. de Morgan had found that when these two species are crossed the characters of the hybrid larvæ are always the same as those of the maternal parent, and this was found by Mr. Fuchs to hold good also when the eggs were kept, during the cleavage period, in sea water with increased and decreased OH ions.[1]

The Gonads of the Urchin Echinocardium cordatum.

Prof. Caullery (Paris) traced the annual cycle of changes in the gonads of this urchin. From July to the end of the year the gonads are almost entirely composed of large cells, each of which contains a vacuole and numerous spherules of reserve substance. In males these cells exhibit, among the reserve material, numerous spermatozoa, agglutinated into pockets, which have been ingested by the cells; in females, fragments of degenerating ova are seen between the cells. At the periphery of the gonad there are either small masses of spermatogonia or oocytes. Growth of the genital products takes place, in part owing to the presence of the reserve-laden cells, at the end of winter, and the period of maturity, at Wimereux, extends from April to the end of May. The reserve-containing cells are gradually pushed towards the centre of the acini, and in some localities, *e.g.* Naples, disappear, but at Wimereux they do not fully disappear. Up to the end of May there have been formed, in the testes, for example, only the sexual cells, but henceforward there are produced numerous cells, each of which elaborates groups of granules and contains a large vacuole. This is the new reserve tissue, which soon forms a continuous peripheral layer. By the end of June the sexual elements in course of formation exhibit signs of degeneration, *e.g.* fragmentation of the oocytes and pycnosis of the spermatogonia, but ripe sexual products are for some time longer emitted. After July the emission ceases, and the sperms remaining in the testis become agglutinated and are ingested by the reserve cells, which gradually occupy the whole gonad. In star-fishes there is no reserve tissue, and the gonads, after having almost filled the arms, become so much reduced as to be almost imperceptible.

Observations on Boring Molluscs.

Mr. W. T. Elliott and Miss B. Lindsay described observations on *Zirphaea* (*Pholas*) *crispata* and *Saxicava rugosa*, made on the shore at St. Andrews, which confirm the statement of Prof. McIntosh that the method of boring of these molluscs is mechanical, and not chemical. Both molluscs work by means of a partial vacuum produced by cooperation between the mantle and foot, supplemented by scraping movements of the shell, which in Zirphæa are continuous and progressive during the time of boring. Reference was made to the importance of boring organisms in connection with coast erosion.

[1] These experiments were prompted by recent work of H. D. Tennent (1909, 1910) who crossed Hipponoe ♂ × Toxopneustes, ♀ and T. ♂ × H. ♀, obtaining in both cases larvæ with a preponderance of Hipponoe characters. By keeping the eggs, during the cleavage period, in sea water with increased and decreased concentration of OH ions he claims to have altered this dominance and states that a decrease of OH ions gave Toxopneustes characters.

The Species of Balanus Collected by the "Siboga."

Dr. P. P. C. Hoek (Haarlem) gave an account of some of the species of Balanus collected in the Malay Archipelago during the cruise of the *Siboga*. Of the twenty-seven species collected, nineteen are new. Few species were brought up from great depths; most of them were taken at a not greater depth than 90 metres. Some were brought up from 564, 289, 216, 275, 304, and 390 metres respectively, but the species represented in the first three cases were collected also at a depth of less than 100 metres. Dr. Hoek described some of the features, especially the labrum, which he had used in classification.

The Renal Organs of Squilla.

Dr. W. N. F. Woodland described the renal organs—maxillary glands—of Squilla. In an Erichthus larva 2 mm. long the gland consists of a short narrow tube, opening externally on the maxilla and ending internally in a slightly dilated end sac. In an older larva, 12 mm. long, the gland has become divided into two thin-walled compartments—the kidney proper and the end sac—lying side by side and communicating by a small aperture at their posterior ends. A little later the walls of the gland become invaginated, forming internal lamellar folds containing extensions of the hæmocœle, a process which continues so extensively that, in the adult, the cavity of the gland is almost entirely broken up into a network of spaces. Other features of the internal anatomy were also referred to, namely, the presence of a well-developed nauplius eye, rectal glands, and a very short proctodæum, which forms a wide cloaca-like cavity.

A Reconstructed Trilobite.

Dr. Malcolm Laurie gave an account of the anterior end of a trilobite (Calymene), which he has studied by means of grinding away definite and very thin layers of the fossil, photographing each exposed surface and reconstructing the specimen in wax on an enlarged scale. He exhibited the reconstruction, and pointed out that, although the mouth has been considered as opening behind the hypostome, the size and form of the latter render it improbable that the mouth opened behind it. Apparently the anterior margin of the hypostome projected ventrally, while the inturned margin of the neighbouring carapace also projected ventrally, the two forming lower and upper lips respectively to the mouth. In a line between the lateral margin of the glabella and the eyes there is a long conical structure, more than two-thirds the length of the carapace, divided into joints by annular thickenings. It is impossible to state certainly whether this is *in situ*, but its structure resembles that of an antenna. If it be such it must have been attached to the body behind the hypostome, as otherwise it could not have been withdrawn when the animal rolled itself up. This appears to be another instance of a post-oral appendage assuming an antennary function, as in Phrynus and Thelyphonus.

British Symphyla and Diplopoda.

Mr. R. S. Bagnall gave a rapid survey of the British Symphyla, pointing out the characters of the genera Scutigerella and Scolopendrella and of some of their species. A year ago only one species of the former was known from Britain; in 1904, when Hansen's monograph of the order appeared, eight European forms were recognised; of these, six have now been found in the north of England, and there have also been discovered four other well defined and apparently new forms. Mr. Bagnall recognises four species of Scutigerella and seven of Scolopendrella. He also recorded four diplopods from the north of England, each of which represents a genus previously unknown to the British fauna, and, from the same locality, a new pauropod, the first British example of the Eurypauropodidæ.

Mimicry in African Butterflies and Moths.

Prof. E. B. Poulton exhibited three groups of mimetic butterflies collected at Entebbe, Uganda. These groups were centred round species of the distasteful family Acræinæ. Among the mimics were species of Acræinæ, showing that members of this family acted as mimics and models, a fact supporting the theory of Fritz Müller as

against that of Bates. There were also acræine mimics which mimicked other species of the same family, themselves mimics of the primary acræine models. The rest of the exhibit was concerned with examples from Lagos, among which was a caterpillar of a well-known moth (Nyctemera), which before becoming a chrysalis secreted and covered itself with a mass of bubbly froth, which on hardening resembled the cocoons of a braconid parasite, and probably acted as a protection against insectivorous birds or lizards.

The Scent Patches of Lepidoptera.

Dr. F. A. Dixey described the scent patches of certain butterflies and their associated tracheæ. The males of many butterflies possess the power of emitting a scent, which is apparently attractive to the female. The scent patches are best distributed in Pierinæ (*e.g.* the orange tip). The apparatus consists of specialised scales scattered over the upper surface of the wing of the male. The scent is elaborated by cells in the wing membrane; the oil enters the specialised scale at its basal foot-stalk, and escapes by fimbriæ at the distal end of the scale. In other cases (*e.g.* the clouded yellow) the scent scales are aggregated into patches, so arranged that, in the ordinary position of rest, the patches of the fore- and hind-wings are coincident. The scales of these patches have neither foot-stalk nor fimbriæ. In some species of Catopsilia there are two specialised scale patches, which Dr. Dixey found to be provided with a special tracheal supply derived from the larger tubes in the wing veins. On reaching the scent patch the main tracheal trunks were found to break up into branches, the ultimate distribution of which was not ascertained, but appeared to bear a definite relation to the scent scales. Dr. Dixey suggested that the tracheæ were concerned in the dispersion of the perfume through the scales, acting in the manner of a *vis a tergo*.

The Biology of Eels.

Dr. Johs. Schmidt (Copenhagen) gave an account of five years' Danish investigations on the biology of eels. These have shown that the biology and reproduction of the conger and eel are more complicated matters than they seemed after the publication of Grassi's work. In the case of the eel, the youngest stages found are 4 cm. in length, and it is therefore not yet possible to state exactly where in the Atlantic the eel spawns, except that it must be outside the continental slope. All the larval stages, even the youngest (but not the eggs), of the conger are known, and it can now be stated that the conger spawns everywhere in the Mediterranean and in the Atlantic west of Gibraltar; how far west is not yet ascertained, but the half-grown larvæ of *Conger vulgaris* have been taken near the Azores. These investigations have not confirmed the earlier suppositions (of Grassi) that the larval development of eels takes place at the bottom of the sea or in great depths. All the murænoid eggs (several thousands) were taken near the surface of the sea, as were also the youngest pre-leptocephalic stages, *e.g.* of *Conger vulgaris* and *C. mystax*. The full-grown larvæ of the eel and conger also occurred in the upper layers. Murænoid eggs were found not only in the Mediterranean, but also right across the Atlantic between 20° and 40° N. lat. Evidently, therefore, some eels spawn there, but how far from the surface has not yet been ascertained. Dr. Schmidt illustrated his remarks by charts and a beautiful series of larval and metamorphosing examples of several species.

The Dorsal Vibratile Organ of the Rockling (Motella).

The dorsal vibratile fin of the rockling, which has been believed to be a lure, is regarded by Dr. J. Stuart Thomson as an organ for producing a current of water over numerous terminal or taste buds situated in the skin of that region of the body, which thus functions as a gustatory organ. These taste organs are distinguished from the lateral line organs by certain structural differences and by the fact that they are innervated by the recurrent facial nerve, the root of which is in the facial lobe of the medulla, which lobe has been described by Herrick as part of the gustatory tract. Dr. Thomson's experiments indicate the existence of a gustatory reaction in the rockling, some of the most successful responses being obtained on placing Arenicola in proximity to, but not in contact with, the taste buds of the region under consideration.

A Remarkable Egg of the Kestrel.

Prof. Patten commented on an egg laid by a tame kestrel, which has been in his possession eight years. The egg is normal in size, but milky-white in colour and almost unspotted except at its larger end; there are spots and blotches of rich purple-brown intermixed with greyish-purple, the whole pigmentation forming a broken zonular band. Dr. Patten suggested that a highly nutritious hearty meal, coming after a fast, and in a warm change of weather, may have toned the bird to such a physiological state that the ovaries became sufficiently active to induce ovulation.

Prof. R. J. Anderson brought forward a number of details regarding the constitution of, and variation in, the manus and pes of Primates, and contributed a note on the manus of a young Indian elephant.

J. H. ASHWORTH.

OLD AND NEW VIEWS ON THE TREATMENT OF CONSUMPTION.[1]

DR. THEODORE WILLIAMS stated that 255 years had elapsed since William Harvey instituted this festival, and that orations had been delivered in Latin or English ever since in commemoration of benefactors, and with Harvey's exhortation to the fellows and members to study out the secrets of nature by way of experiment, and to continue in mutual love and affection among themselves. He then proceeded to review the various steps of Harvey's great discovery of the circulation of the blood, and remarked that its author, in spite of the severest criticism, lived to see it firmly established in the annals of medicine and to witness the conversion of the greater number of his opponents. The seed sown by this discovery, based on observations and experiments, and put forth with convincing logic by this most accurate observer, had revealed to the world further scientific truths, which have been elaborated by Harvey's successors in the arts of medicine and of surgery, and have brought forth a harvest of improvements—physiological, clinical, pathological, and therapeutical—which added immensely to the total sum of human health and happiness. Dr. Williams instanced as examples the administration of anæsthetics, intravenous and hypodermic injections, and treatment by vaccines, while auscultation and the graphic methods of measuring blood pressure and rhythm might also be counted as outcomes of the knowledge initiated by Harvey's discovery.

Harvey's views on tuberculosis are not known, though his lost "medical observation" may have treated of these; but the lecturer sketched the doctrines held by his contemporaries on this subject, and the treatment in vogue, the former being somewhat obscure and the latter mingling with hygienic and dietetic rules, which were to some extent reasonable, prescriptions containing woodlice, crabs' eyes, the simple powder of crabs' claws, red coral and white amber in the form of powders or julep to "temper the sharpness of the blood." The Royal touch for the King's Evil continued to be believed in until a much later date. Most of the theories of that time assigned the cause of consumption to errors of digestion or in the formation of lymph or chyle or blood, or to defective respiration; but they chiefly dwell on the inflammatory origin, and though long suspected, the *vera causa*, viz. the tubercle bacillus, was never definitely proved until Robert Koch appeared on the scene. Laennec and other observers had meantime given scientific accounts of the morbid anatomy of tubercle, and the treatment had changed from an anti-inflammatory *régime* depending largely on blood-letting to a tonic and building-up system,

[1] Abstract of the Harveian Oration delivered at the Royal College of Physicians on October 18 by Dr. C. Theodore Williams.

fortified by a liberal dietary, by the use of cod-liver oil and by climatic treatment.

Dr. Theodore Williams, at the express wish of the president of the college, proceeded to sketch the evolution of the treatment of consumption as it had come under his own cognisance during his nearly fifty years of professional experience. He spoke of the effects of climate, and especially of that of high altitudes; then of the open-air life which had first been advocated in England by Bodington and Henry MacCormac, and was now accepted as essential in cases of tubercular disease. Dr. Williams had personally studied the climates most advantageous for the treatment of consumption in the New and the Old Worlds, and had given a full trial to mountain climates, having recorded their effects on more than 400 of his private patients, and studied the results of the diminished barometric pressure, of the diathermancy of the air, and of the asepticity, or freedom from pathogenic germs, which are characteristic of high-altitude climates.

He found the effects on selected cases of chronic tuberculosis remarkable: many symptoms vanished, and muscular power increased largely, while the local improvement was even more striking, and in many early cases of consolidation the disappearance of physical signs was so complete that the physician had to refer to his notes to discover which lung was originally attacked! In fact, the high-altitude cases yielded the most favourable results of all his statistics, and, what is more important, the fewest relapses.

He then noticed the establishment and spread of sanatoria all over the world, and said that in Germany alone the insurance societies now maintain more than 16,000 beds for the working classes; and he directed attention to the methods pursued, including rest, with or without Liegehalle, good feeding, graduated exercise, and labour supervised to meet individual requirements, which have all been tried at different sanatoria, giving the results achieved thereby. He described the system pursued at some of the best English institutions, where the patients with limited tuberculous pulmonary lesions, when removed to thoroughly hygienic surroundings and compelled to lead a healthy life, their food, exercise, and rests being under minute skilled direction, may slowly and gradually recover, and, losing symptoms, be able to return home to active working life, ready and able to instruct those around them in the gospel of fresh air and wholesome living.

But Dr. Williams emphasised the need for discovering and treating *early* cases of the disease, and though agreeing in the general truth of the curability of consumption, he felt obliged to except the acute cases, which, however, fortunately form a very small percentage of the whole.

He contended that the pressing need is for more hospitals for consumption—England had been a leader in establishing these, and now it is recognised that the consumption hospital is required as a centre from which to draft off cases suitable for sanatoria, as well as for the treatment of more advanced and acute cases, which are thus isolated from the rest of the population and prevented from becoming centres of infection.

Dr. Theodore Williams spoke of the modern treatment of consumption by anti-tuberculous serums and vaccines, and gave the experience of others and of himself, concluding by the remark that everything points to the necessity for further investigation, and that such investigation can be best carried on in hospitals and sanatoria, where trained observers minutely watch the effect of tuberculin on the patient's system and control the inoculations and their results. He summed up with a bird's-eye view of the present state of the crusade against tuberculosis in this country and our means of pursuing the fight.

He reminded his audience of what had already been done by the blessed agencies of prevention, such as improved drainage, more cubic space, and less overcrowding, better food and more of it, more air and sunlight, cleanliness of house and person, and increased opportunities for play and exercise, and how, mainly by these means, the phthisis mortality had been reduced two-thirds in fifty years.

A good town-planning scheme should prove a fine weapon in the hands of the combatants. Education of all classes, including the children, must be promoted, and that with the tuberculosis exhibitions and popular lectures and tracts which now permeate and enlighten the country, will be found to be trusty armour and show the people how they can help themselves.

Prevention is naturally what is to be aimed at; but for the consumptives who are now among us are needed as links in the chain:—

(1) Well-equipped consumption hospitals to receive and isolate acute and advanced cases.

(2) The dispensary system, introduced by Dr. Philip, and now at work in several metropolitan boroughs, which, with the out-patient departments of consumption hospitals, can classify the patients, visiting them and contacts in their own homes, and connecting them with local government and philanthropic agencies.

(3) The sanatorium, and especially those institutions which make a feature of preparing the patient by various grades of labour for return to a workaday world.

(4) Labour colonies and exchanges to assist in the rehabilitation of those who have been smitten with the disease, or may be more liable to reinfection, or may require the safeguard of a changed and more healthy occupation.

The task of further reducing, and finally abolishing, tuberculosis is not a hopeless one, but it does not lie wholly with the doctors. It lies also with those who have it in their power to remove and lessen the principal causes of tuberculosis, viz. the overcrowding of our cities, the want of open spaces and of ventilation, the insanitary houses, the disgusting habit of spitting, and the lack of a good supply of water and of pure milk. Philanthropists, together with local government authorities administering under our Minister of Health, might remedy these defects and ensure that the number of phthisis cases should be in future comparatively small.

The great Harvey would smile with pleasure as he realised our successive advances in knowledge and the attempts to remedy our deficiencies, and he might well receive our laurel crown as the leader who showed the way to those who are now searching out the secrets of nature by way of experiment.

UNIVERSITY EDUCATION IN ENGLAND AND WALES.

ATTENTION has been directed already (NATURE, September 21, vol. lxxxvii., p. 407) to the Blue-book containing the reports for the year 1909–10 from those universities and university colleges in Great Britain which participate in the Parliamentary grant for university colleges. In the notes referred to, information was given as to the amount of the Treasury grant, particulars concerning the incomes of the various colleges, and similar data.

An introductory report by the Board of Education, with which the volume opens, contains much that deserves careful study by all who are interested in the progress of higher education. A number of extracts from this prefatory memorandum are subjoined.

The weakness of the appeal which university education makes in the present day to the imagination of the wealthy finds its counterpart in the apathy of the public at large, and this apathy is only too frequently reflected in the attitude of the local authorities. Some of the most important of these give far less than their proper share of support to the universities, and in one or two instances the maintenance at their present level of the grants made by local education authorities has been endangered. On the other hand, in two instances there has been a notable increase in the amount of the support received from this source. As the result of representations made by the Right Hon. Joseph Chamberlain, M.P., the Chancellor of the University, the City of Birmingham has promised to increase

its grant in aid of the University of Birmingham from ½d. to 1d. rate. The exact amount of increased support thus given to the University is, however, for the moment uncertain, because the University has been required by the municipality to devote an as yet indeterminable portion of the additional grant to the establishment of maintenance allowances and scholarships to poor students. Since the fees paid by students never equal the cost of the education they receive, it follows that the net amount of the increased aid to the University will be something less than the difference between the gross increase and the sum devoted to maintenance allowances and scholarships. If, as there is reason to hope will be the case, the grant is continued at the higher level for future years, the extension of the boundaries of the city will lead to a further increase in the amount received by the University unless this additional income has to be expended on scholarships or bursaries. The Corporation of Newcastle-upon-Tyne has recently made an additional grant of 1500*l.* a year for five years to Armstrong College. This additional grant is the more noteworthy because it has been made for the special purpose of developing the faculty of arts, a faculty which does not, as a rule, appeal so directly to local sympathies as do the faculties of pure and applied science.

The problem of university education in the metropolis does not grow easier as time advances; the need for that help and guidance which only a well-organised university can afford increases yearly. The many independent institutions and authorities working in the field of operations are conscious, each in its own way, of the growing demand for instruction of a high order, and of the urgent necessity for increased means of providing it, and it is not to be wondered at if they attack the problem as best they may, without considering too closely the effects of their action upon their neighbours. Yet no satisfactory issue is possible on these lines. The Board is endeavouring for the moment to avoid encouraging this confusion, but nothing really far-reaching can be attempted until after the Royal Commission appointed in 1909 has completed its labours.

This need for a proper scheme of coordination is perhaps especially urgent in the case of higher technological and professional work; it is not confined to London. Until the problem has been adequately dealt with, it is almost impossible to deal wisely with even the most urgent claims for further development. Yet there is undoubtedly a great need for considerable further provision of the highest type of instruction. The fifth annual report of the British Science Guild contains certain rough comparisons between the number of properly equipped day students attending the *technische Hochschulen* in Germany and the numbers of day students doing work of a kind more or less comparable in this country. The comparison shows that after making full allowance for the larger population of Germany, there are more than twice as many such students in Germany as in Great Britain and Ireland. If the inquiry could be more exact, and if only those students in this country were included who had received the same amount of previous general education, and were giving the whole of their time to higher technical studies, it is certain that the comparison would be even less favourable.

But if the problem in regard to technology is to discover how to make a wise increase in the amount of provision without the incidental waste which comes from unnecessary overlapping between competing institutions, the problem in connection with medical education is quite different. What is needed here is concentration and coordination of effort and the greater efficiency that will then alone be possible. There is probably more than sufficient provision made for medical education in these islands; it is a question whether, even now, after years of shrinkage in the numbers of men entering the medical profession, the output is not still in excess of the national needs. Nowhere is this excess of provision more evident than in the metropolis. The difficulties inherent in the position are obvious, particularly at the present moment, when public opinion has not yet been fully informed as to the true relationship between the hospital and the medical school, or as to the invaluable services which a progressive school renders not only to the treatment of the sick poor, but also to the national medical service. To the closeness of this relationship, on the other hand, is due the facilities for access to clinical study which London offers to a greater degree than any place in the world. Any change which endangered this advantage would be very dearly bought.

Of the twenty-three general medical schools in England, all but five (including Oxford and Cambridge) have now applied to the Board for grants in aid of the instruction they give. It is hoped it may be possible to include in the next volume of these reports returns from the medical schools in receipt of grant from the Board analogous to those now received from universities and university colleges in receipt of aid from the Exchequer. It is not unreasonable to anticipate that these reports will afford a valuable basis for a general consideration of the many problems in regard to medical education existing at the present time.

Reference was made in the introductory report last year to the tutorial classes which have been established on the initiative of the Workers' Educational Association. Although, as explained in that report, the education given in these classes cannot properly be called university education, yet the universities have throughout been so closely connected with their organisation that some further reference to them seems not inappropriate. During the current session there are nearly seventy of these classes at work, or nearly double the number in existence last session. The rapid growth of the classes continues to afford undoubted evidence of the extent to which they are meeting a real need. Further development was made last year, when a summer school was established for the first time. The school was held in Oxford during July and August, and was intended for students who had attended tutorial classes during the previous session. As students could only remain for a week, or at most a fortnight, the lectures and instruction for each week were arranged to deal with a particular subject or group of subjects. An important part of the students' work consisted in writing essays, which were subsequently read and discussed with special tutors. The arrangements were necessarily somewhat experimental, but there seems little doubt that the students greatly appreciated the establishment of the school, and derived much benefit from it. Grants were paid by the Board of Education in aid of the classes held during the session 1909–10, and also in respect of the summer school. During the session the Board arranged for a special inspection of some of the classes, and the report was subsequently made public. The report fully confirmed the high opinion already existing as to the value of the classes.

The accompanying table presents an analysis of the students under instruction in England and Wales during the academical year 1909–10. The revised form in which the returns of students has been compiled by the universities has rendered it possible to make this table more detailed than before. The table also gives more accurate figures than have been hitherto available as to the number of students being prepared by university institutions for matriculation examinations.

The number of part-time students of all kinds in England reaches the large figure of more than 13,700, or more than half again as large as the number of whole-time day students. Only about 1200 of these were reading for degrees or attending post-graduate courses. A considerable proportion of the remainder only attended short courses; but even so it is evident that there is as yet no sign of any relative decrease in the demand being made upon the universities for work which, excellent and useful as it is, cannot be described as university work in the strict sense of the term. It is to be hoped that as time goes on, and as the secondary schools of the country make their influence more clearly felt, the relative growth in the number of full-time students properly equipped for university studies will increase.

The number of day students under seventeen is but 2·5 per cent. of the total, and the number under eighteen is less than 10 per cent. of the whole number of day students. These figures are encouraging, and as compared with the figures for ten years ago, if these could be obtained, would probably show an increase in the age at which the majority of the students are entering upon university courses now. In proportion as the length of school life in the secondary schools increases, the percentage of day students entering the universities under

[1] Eight of these were students in training who were reading for the Teachers' Diploma (post-graduate).
[2] Twenty-five of these were following degree courses though they had not matriculated.

eighteen will probably fall. In Wales secondary education has been organised for a greater length of time than in England, and this is probably one of the causes for the smaller percentage of day students under eighteen in the Welsh colleges.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—At the annual general meeting of the Philosophical Society, held on Monday, October 30, the following were elected officers:—*President*, Prof. Sir George Darwin; *vice-presidents*, Prof. Newall, Prof. Hopkinson, Prof. Wood; *treasurer, Prof. Hobson*; *secretaries*, Dr. Barnes, Mr. A. Wood, Mr. F. A. Potts; *members of council*, Prof. Sir J. Larmor, Prof. Biffen, Prof. Pope, Mr. R. H. Rastall, Mr. K. Lucas, Mr. E. A. Newell Arber, Prof. Sir J. J. Thomson, Mr. J. E. Purvis, *The Master of Christ's*, *Mr. R. P. Gregory*, *Dr. Cobbett*, and *Mr. J. W. Mercer*. The names of the new members of the council are in italics.

At Christ's College, Dr. H. J. H. Fenton, F.R.S., and Prof. E. W. Brown, F.R.S., of the Yale University, have been elected honorary fellows. The same honour has been conferred at Emmanuel College on Mr. R. H. Biffen, prælector in agriculture, and on Mr. F. G. Hopkins, F.R.S., prælector in biochemistry at Trinity College, formerly fellow and tutor of Emmanuel.

T. G. Bedford has been appointed demonstrator of experimental physics, and J. A. Crowther and H. Thirkill assistant demonstrators.

The electors to the Allen scholarship give notice that they are prepared to receive applications from candidates. Any graduate of the University is eligible for the scholarship provided that his age on the first day of the Lent term 1912 does not exceed twenty-eight years. This year the scholarship is open to candidates who propose to undertake research in any branch of study which comes within the department of any of the following special boards:—medicine, mathematics, physics and chemistry, biology and geology. The emolument of the student is 250*l*., or such smaller sum as the fund, after payment of all expenses, shall be capable of providing. Candidates must send their names to the Vice-Chancellor on or before February 1, 1912.

The electors to the Isaac Newton studentships give notice that an election to a studentship will be held in the Lent term, 1912. These studentships are for the encouragement of study and research in astronomy (especially gravitational astronomy, but including other branches of astronomy and astronomical physics) and physical optics. The persons eligible are members of the University who have been admitted to the degree of Bachelor of Arts, and are under the age of twenty-five years on the first day of January, 1912. The studentship will be tenable for the term of three years from April 15, 1912. Candidates for the studentship are invited to send in their applications to the Vice-Chancellor between January 16 and 26, 1912.

The special board for biology and geology gives notice that the Gedge prize will be offered for competition in the Michaelmas term, 1912. The prize will be awarded for the best original observations in physiology. The essays are to be sent to the professor of physiology not later than October 1, 1912. The examiners may require every candidate to deliver his essay in the form of a lecture.

OXFORD.—The statute exempting candidates for honours in mathematics and natural science from compulsory Greek is approaching its final stages. On Tuesday, November 7,

it will come before Congregation, as amended in the course of last term. Should it pass Congregation, it will be submitted to Convocation, upon the decision of which depends its ultimate destiny. The date of the final struggle has not yet been made public, but it is practically certain that the present term will see the close of the long controversy.

THE board of trustees of Stanford University has announced, says *Science*, a gift of 2000*l.* made by Prof. Adolph Barkan, San Francisco, professor emeritus of the medical school, for the establishment of a special library dealing with diseases of the eye, ear, nose, and throat. A gift of 1000*l.* from Charles C. Stanford for medical library purposes is also announced.

AT the meeting of the council of the Royal Agricultural Society, held on October 25, the Duke of Devonshire reported the special committee's recommendation that the society's gold medal should be offered for original research on any agricultural subject or any of the cognate agricultural sciences. The medal will be awarded for a monograph or essay giving evidence of original research, and candidates must reside in Great Britain or Ireland, and must not be over the age of twenty-seven years or of more than five years' standing from the time of taking their first agricultural qualification, the qualification being a degree or diploma of a university or university college, or the National Diploma in Agriculture.

WE learn from *The British Medical Journal* that a new university has been founded by the United States in the Philippine Islands. There was already a University of St. Thomas, founded by the Spaniards in 1611, but it was thought that this old institution did not meet modern requirements. The new university comprises a college of medicine and surgery, which was opened in 1907, besides colleges of veterinary science, of agriculture, of the liberal arts, of law and political science, and of engineering. The seat of the new university is Manila. A clause of the Act founding the university is to the following effect:—"No student shall be denied admission to the university by reason of age, sex, nationality, religious belief, or political affiliation."

THE annual meeting of the Association of Teachers in Technical Institutions will be held at the Borough Polytechnic, Borough Road, S.E., on Saturday, November 4, the president, Mr. Barker North, in the chair. The annual report of the council, which will be considered at this meeting, deals with the large increase in the membership of the association in the past year, and with active work during that period. Branches have been formed in Ireland and Wales, so that the activities of the association now spread over the whole kingdom. After the consideration of the report a discussion will be initiated on the Board of Education examinations in science, by Mr. C. F. Smith, Manchester School of Technology, and Mr. J. Wilson, Battersea Polytechnic. To this discussion visitors are invited. Particulars can be obtained from the honorary secretary, Mr. P. Abbott, The Polytechnic, Regent Street, W.

THE Association for the International Interchange of Students is a body which exists to promote the intelligent study of other countries by the university students of Great Britain and the colonies. The organisation arranges tours during which students are brought into contact with the leading cities and citizens abroad, and are thus enabled to study at first hand the social, political, municipal, and university life of other countries. The first annual report contains reports of speeches made by some of the students who have availed themselves of the advantages the association offers, and gives ample evidence of the value of the movement. In addition to putting any class of student in touch with the best sources of information, the secretary, Mr. W. H. Crees, has succeeded in modifying the expenses of travel. Unfortunately, like many other institutions, the association has suffered from lack of funds, and is unable to carry out the proposal of travelling scholarships which were first of all contemplated.

THE Imperial Conference of Teachers' Associations convened by the League of the Empire is to be held on July 12–16, 1912. The list of agenda includes a variety of subjects, such as the training of teachers (professional and university); the recognition throughout the Empire of teachers' certificates; the migration of teachers for purposes of study generally and for temporary interchange of appointments; coordination in education; and the working of the scholarship system in different parts of the Empire. Besides these subjects, technical education in its relation to local industries and as a preparation for general scientific and trade research; the place of history and geography in education; the English language and literature; and physical education, will form subjects of discussion. Overseas teachers in particular will consider the best means of organising a rural school. Suggestions are constantly being received from overseas teachers' associations. It has been proposed to illustrate the agenda with observation work, and illustrated lectures will be introduced both before and after the conference. A short course of travel-study in England is also being prepared.

A COPY of the first volume of the calendar for 1911–12 of the University of Sheffield has been received. It contains full particulars concerning all the courses of work in the various faculties and the conditions under which the different degrees of the University are conferred. The arrangements in the faculty of applied science are of especial interest. These departments provide lecture and laboratory courses of instruction in the subjects of applied science required in the engineering, metallurgical, mining, and building industries. Students are in certain circumstances permitted to qualify for degrees in part by evening study. For example, students employed during the day in some metallurgical works or laboratory approved by the faculty are permitted to qualify in part by evening study for the degree of Bachelor of Metallurgy. We notice, too, that the council of the Institution of Civil Engineers recognises, under certain conditions, the degree of Bachelor of Engineering of this University as exempting from the institution's examination for associate membership. An arrangement has been made also with the Imperial College of Science and Technology by which the University of Sheffield is recognised as being in association with the Imperial College for such of their students as may desire to specialise in the study of the metallurgy of iron and steel for the associateship of the Royal School of Mines.

THE new laboratories at Shrewsbury School were formally opened on October 20 by Mr. Francis Darwin, F.R.S., who gave an address in the school hall, Lord Barnard presiding as chairman of the governing body. In order to emphasise the present attitude of the school towards science, Mr. F. Darwin repeated the well-known story of his father as a Shrewsbury boy being publicly rebuked by Dr. Butler, the headmaster, for wasting his time in the study of chemistry at home in an improvised laboratory. The contrast between this state of things and the present curriculum, in which every boy in the school has to go through a course of practical scientific training, is sufficiently striking. The need for new laboratories is due to the prominence given to science by the headmaster, Mr. Alington, and at the present time 270 boys are passing through the science school under the guidance of five masters. The recent additions, which have been named the Darwin Buildings, consist of three rooms, two for physics and chemistry, respectively, and the third for nature-study and physical measurements, and all are excellently fitted for their various purposes. At the end of his address Mr. F. Darwin pointed out that the method adopted in the science school at Shrewsbury is in harmony with the motto of the Royal Society, *Nullius in verba*, since the essence of laboratory work is that the pupil learns by observation and experiment rather than from the assertions of his teacher.

DR. ALFRED MUMFORD, in his annual report as medical officer to the governors of the Manchester Grammar School, states that he has been able to compare the physical development during the last five years (*i.e.* since the influence of the presentation of free scholarships to boys from the elementary schools has become felt) with the physical development of the boys of a generation ago, viz. during the period of 1881–6. He finds there has been a remarkable gain in nearly all directions, especially as regards height and weight, amounting to more than 1 inch in height between the ages of thirteen and sixteen,

and to an average increase of more than 4 lb. in weight. At the age of sixteen the boys are $1\frac{1}{2}$ inches taller and 8 lb. heavier than a generation ago. The improvement is less marked at seventeen and eighteen years of age, and disappears in those who stay until nineteen. These calculations are based on more than 6000 measurements. This remarkable change probably has many causes, chief among them being the steady diminution or postponement of early infectious disease in childhood, due to the progressive operation of the Public Health Act of 1875. A second factor of equal, if not greater, importance has been the changed attitude towards athletics and physical exercise, particularly during the younger ages, that prevails throughout the school to-day. Other causes of the general improvement in physique are the better housing, the increased knowledge and better use of foods, and the greater insight into the meaning of parental responsibility as regards health, which are certainly affecting a considerable number of homes at the present day. In order to test the question as to whether the free scholars—two-thirds of whom come from the elementary schools—are of inferior physique to their companions, comparisons, based on 250 cases, were made between the two at successive years of life, and it is found that, though the "free scholar" is slightly smaller at eleven, twelve, and thirteen, yet by the age of fourteen he has equalled his companions in height, and in some cases surpassed them.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Microscopical Society, October 18.—Mr. H. G. Plimmer, F.R.S., president, in the chair.—T. W. **Butcher**: Structural details of *Coscinodiscus asteromphalus*. A paper describing the primary areolations with the secondary and tertiary markings, illustrated by a series of lantern-slides made from photomicrographs obtained at a magnification of 1100. In addition, slides were shown demonstrating a fine siliceous network, or veil, lying upon the outer surface of the valve, and others in series, from photomicrographs taken, at 5 or 6 consecutive foci, of the hexagonal cell layer with its "ringed" openings of Morland, to prove that these openings are clear and not obstructed by the finely perforated membrane recently reported by Mr. Nelson (Journ. Roy. Micro. Soc., October, 1910). The membrane being non-existent, its value as a test for a high-power lens is *nil*.—Rev. Hilderic **Friend**: New British enchytræids. *Enchytraeus minimus*, Bret., was described in the *Rev. Suisse de Zoologie* in 1899. Michaelson in *Das Tierreich*, 1900, suggested that it might be one with *E. argenteus*, Mich. (=*E. parvulus*, Friend). Bretscher examined the subject again in 1902, and decided that the two were distinct. The author, who had already described *E. argenteus*, has found *E. minimus* at Buxton, and holds with Bretsche. *Fridericia peruviana*, n.sp., was received in earth from Peru, and submitted to the author by the authorities at Kew. It is 5–6 mm. in length, and has two to five setæ, which are somewhat larger behind than before. Brain slightly concave posteriorly; œsophagus sharply marked off from intestine; dorsal vessel postclitellian in origin, with dilatations in segs. 7–9. Salivary glands not branched; long.—Walter **Bagshaw**: Instantaneous exposure in photomicrography. Flashlight illumination has been put to a novel use by Mr. Bagshaw for the photography through the microscope of objects in motion. A good negative of fresh-water polyzoa (*Lophopus crystallinus*) expanding its tentacles was secured by a charge of "Agfa Flashlight Powder" in one-thirtieth of a second. Gatherings of pond life, such as diatoms, larvæ, water fleas, also yielded successful results. Provision was made for replacing the ordinary lamp by flash powder put in the position previously occupied by the centre of flame, and ignition made with a red-hot wire.

MANCHESTER.

Literary and Philosophical Society, October 17.—Prof. F. E. Weiss, president, in the chair.—H. J. **Woodall**: Mersenne's numbers. In 1644 Mersenne published a book entitled "Cogitata Physico-Mathematica," in which it was stated that certain numbers obtained by raising 2 to the power p, where p is a prime number not greater than 257, and subtracting unity from the result, would be factorisable except in twelve specified instances. He left no clue as to how he arrived at this result, nor is any method known by which he could have done so. Subsequent examination has shown that the statement is incorrect in two cases, one case being prime where he said composite, and the other the reverse, but most of those which, according to him, are factorisable, have been proved to be so. Mr. Woodall gave a proof that the number obtained by subtracting unity from the 181st power of 2 is divisible by 43,441, the quotient containing fifty figures. He explained the method by which the divisor had been arrived at, and stated that the number of unproved cases is now reduced to sixteen (fifteen composites and one prime) out of a total of fifty-six.—S. **Hirst**: A collection of Arachnida and Chilopoda made by Mr. S. A. Neave in Rhodesia north of the Zambezi. The paper deals with the scorpions, Pedipalpi, Solifugæ, and centipedes collected by Mr. Neave. Four new species are described, two of which were obtained by Mr. Neave, the remaining two being specimens in the British Museum, that were obtained from the same area. The new species present no features of special interest, differing only in certain details of the appendages from already known forms. Two of the species obtained by Mr. Neave had only been captured once previously, and are thus of interest from this point of view.

PARIS.

Academy of Sciences, October 16.—M. Armand Gautier in the chair.—Ch. **Bouchard**: The velocity of parachutes. A certain time after starting a parachute the velocity becomes uniform, and this velocity depends on the ratio of P, the weight, and S, the horizontal projection, of the carrying surface. The application of the ordinary resistance formula for air, in which the resistance depends on the square of the velocity, to these measurements, gave unsatisfactory results, but a formula involving the square root of the cube of the velocity (V^3) was found to agree well with the experiments.—M. **Borrelly**: Observations of the Beljawsky comet (1911*g*) made with the comet finder at the Observatory of Marseilles. The positions are given for October 1 and 2. On October 1 the comet was very bright, and visible to the naked eye. The tail was well marked, and extended about 15° from the nucleus. On the following day the appearance of the comet had completely changed, the nucleus being surrounded by a circular halo, two aigrettes showing on the right and left.—M. **Nicolau**: The variation in the movement of the moon.—A. **Demoulin**: The R and ν surfaces.—Etienne **Delassus**: The non-linear linkages and the movements studied by M. Appell.—Marcel **Brillouin**: An interferential method for the determination of the moduli of torsion of crystals. The deformation of the surface of a crystal plate under flexion can be studied by means of the interference fringes, the measurements being made with a metallographic microscope under a low magnifying power. It is shown that all the moduli can be calculated from such measurements.—Georges **Claude**: The volatilisation of the electrodes in neon tubes. It has been shown in a previous note that the gases obtained by the treatment with nitric acid of the film of volatilised metal contain, besides neon, a considerable proportion of helium. Three hypotheses may be put forward to account for this fact: the possible selective action of the volatilised metal on helium contained in the neon in a proportion too small to be detected by the spectroscope, the transformation of neon into helium, or the possible transformation of a portion of the neon into compounds retained by the nitric acid. The experiments described in the present paper support the first of these hypotheses, the selective action of the metal, and this conclusion is in accord with the results of Ramsay and Collie arrived at in a different way.—A. **Rosenstiehl**: The theory of complementary colours.—P. **Janet**, F. **Laporte**, and R. **Jouaust**: The determination of the electromotive force in absolute measure of the normal Weston element. In an earlier publication the electromotive force of the Weston cell had been found by the authors to be 1·01869, in terms of the true ampere and the international ohm. Comparison of the ohm used with those of foreign laboratories reduces this figure to 1·01859,

and a recalculation of the constants of the electrodynamometer used causes a further reduction to 1·01836 (at 20° C.), a value only slightly higher than values obtained in other laboratories.—Albert **Colson**: The theory of solutions. An adverse criticism of the van 't Hoff-Arrhenius theory of solutions.—L. **Gay**: The expansibility pressure of a normal fluid.—Marcel **Delépine**: The volatility of sulphur compounds. Many examples are known in which the replacement of oxygen in a compound by sulphur causes a lowering of the boiling point, and there is a general impression that this is always the case. The author suggests that the substitution of sulphur for oxygen always raises the boiling point of a compound, except in the case of the hydroxyl group of water and the lower alcohols, phenols, and acids.—Henri **Martin**: A human skeleton found in Charente (see p. 16).—R. **Lacasse** and A. **Magnan**: A bicephalous human monster.—Louis **Roule**: Some larvæ of apodal fishes.—R. **Koehler**: Antarctic echinoderms arising from the expedition of the *Pourquoi-Pas?*—Henry **Hubert**: An attempt at a geological map of western Africa.—Ch. **Moureu** and A. **Lepape**: The spectrophotometric estimation of xenon. Constancy of the xenon-argon and xenon-krypton ratios in natural gaseous mixtures. The basis of the method is the increase of intensity of the blue indigo xenon line 4671·4 when the proportion of xenon is increased in a mixture of xenon and argon.—M. de Montessus **de Ballore**: The application of the Cardan suspension to seismographs.

October 23.—M. Armand Gautier in the chair.—Remarks by the president on the work of De Romas, whose statue has just been erected at Nérac.—A. **Müntz** and E. **Laine**: The ammonia in the rain and snow at the observation stations of the Charcot expedition. The estimation of ammonia in eighteen specimens of snow and rain water showed that the distribution of ammonia in rain and snow in the Antarctic regions does not greatly differ from the amounts found at European stations.—Ch. **André**: The cosmogony of Laplace. A criticism of some calculations published by T. J. J. See adverse to the theory of Laplace. The author holds these conclusions to be untenable.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the third quarter of 1911. Observations were possible on sixty-nine days. The results are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—J. **Bosler**: The spectrum of Brooks's comet. Three negatives were taken with exposures of twenty-five minutes, one hour, and one hour thirty-five minutes, the comparison spectrum employed being that of Vega. Besides the hydrocarbon and cyanogen bands there was a group of lines of wave-lengths 407, 405, 401, and 399. The spectrum of the tail was quite different from that of the head, and resembles the spectrum of the tail of the Daniel comet.—M. **Iniguez**: Observations of the Brooks comet made at the Observatory of Madrid.—Henri **Villat**: Certain integral equations of a new type and some problems relating to them.—E. **Jouguet**: The dynamical adiabatic law in the motion of wires.—Georges **Claude**: The commercial manufacture of pure nitrogen. In the preparation of calcium cyanamide by the action of nitrogen upon calcium carbide at a high temperature a very pure nitrogen is required. The quantities required on the large scale are such that chemical methods of preparation are out of the question, and the present paper gives an account of the method of preparing nitrogen by the fractional distillation of liquid air. It is necessary that the nitrogen produced should contain less than 0·25 per cent. of oxygen. Three installations of the type described in the paper have been set up, giving nitrogen of a purity of 99·7 to 99·8 per cent.—Jean **Villey**: The electric couple in electrometers.—Eugène **Fouard**: The osmometry of saline solutions and the ionic theory of Arrhenius. An account of experiments made with a differential osmometer against saccharose as a standard. The results with potassium sulphate are in accord with the Arrhenius theory; with potassium chloride, copper sulphate, and barium chloride, on the other hand, the results found are opposed to the ionic theory.—G. **Darzens** and H. **Rost**: The syntheses of some new hydroaromatic ketones. The chloride of the hydroaromatic acid is prepared by the action of $SOCl_2$, and this, diluted with ether, is treated with the organo-magnesium compound at a temperature of −10° C. The ketone, which is mixed with a small quantity of tertiary alcohol, is purified by conversion into the semicarbazone; the yields are good, from 40 to 60 per cent. Details are given of the preparation and properties of several ketones.—M. **Marage**: Various kinds of deaf-mutes.—Ch. **Gravier**: Some biological peculiarities of the annelid fauna of the Antarctic seas.—E. **Roubaud**: The evolution and history of the "Ver du Cayor," an African larva from the skin of *Cordylobia anthropophaga*.—Maurice **Piettre**: The melanic pigments of animal origin. The pigment was isolated from material from the horse, avoiding the use of strong acids or alkalis in the separation. Analyses of the pigment are given and of the substance derived from it by hydrolysis.—Stanislas **Meunier**: The chemical and lithological examination of the El Nakhla meteorite. This meteorite belongs to a new type allied to Chladnite, from which it differs by the substitution of hypersthene for eustatite.—J. **Thoulet**: The fall of sediments in oceanic waters.

MELBOURNE.

Royal Society of Victoria, September 14.—Prof. E. W. Skeats in the chair.—E. F. J. **Love** and G. **Smeal**: The psychrometrical formula. A modified formula for the wet- and dry-bulb hygrometer was suggested by Ekholm in 1908, viz. $x=\eta f-AB(t-t')$, where η is a proper fraction to allow for diminution of vapour pressure by hygroscopic action of the material on the wet bulb. The facts do not require any such interpretation, and the formula is tested by observations with several wet bulbs covered with different materials. A new large type of screen was used, and simultaneous readings show no difference to temperature, as would be the case if such action occurred; further, by comparison with a Regnault hygrometer, the value of η is found by least squares to be unity, confirming the usual theory.—Howard **Ashton**: Some new Australian Cicadidæ. The specimens come from northern Australia. The following are new:—*Cyclochila laticosta*, *Psaltoda pulchra*, *P. fumipennis*, *Macrotristria doddi*, *Owra insignis* (n.g. et n.sp.), *Thaumastopsaltria glauca*, *Melampsalta brevis*, *M. viridis*, *M. crucifera*, *Pauropsalta elgneri*, *P. subolivacea*, and *Prasia vitticollis*.—Prof. **Skeats**: Specimens from Heathcote showing all stages of metasomatism from diabase to quartz.—T. S. **Hall**: Graptolites from Preservation Inlet, west coast of New Zealand. These are of Lancefieldian (lowest Ordovician) age; Bryograptus, Clonograptus, and other genera are present. A most remarkable fact was the exact lithological resemblance of the rock, a blue-black silicified shale, to that of Lancefield (Victoria), though the localities are some 1200 miles apart.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 2.

ROYAL SOCIETY, at 4.30.—Colour Blindness and the Trichromatic Theory of Colour Vision. Part III. Incomplete Colour Blindness: Sir W. de W. Abney, K.C.B., F.R.S.—Note on the Iridescent Colours of Birds and Insects: A. Mallock, F.R.S.—The Behaviour of the Infusorian Micronucleus in Regeneration: K. R. Lewin.—An Inquiry into the Influence of the Constituents of a Bacterial Emulsion on the Opsonic Index: A. F. Hayden and W. P. Morgan.—The Morphology of *Trypanosoma gambiense* (Dutton and Todd): Colonel Sir David Bruce, C.B., F.R.S.—(1) Factors in the Interpretation of the Inhibitive and Fixation Serum Reactions in Pulmonary Tuberculosis; (2) Preliminary Report upon the Injection of Rabbits with Protein-free (Tuberculo-) Antigen and Antigen-Serum Mixtures: A. H. Caulfeild.

MONDAY, NOVEMBER 6.

SOCIETY OF ENGINEERS, at 7.30.—Two-cycle Engines: R. W. A. Brewer.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Norsemen in America: Dr. Fridtjof Nansen, G.C.M.C.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Deflocculation as Affecting Lubrication: Dr. E. G. Acheson.

TUESDAY, NOVEMBER 7.

INSTITUTION OF CIVIL ENGINEERS, at 8.—President's Address.

RÖNTGEN SOCIETY, at 8.15.—Presidential Address: Alan A. Campbell Swinton.

ZOOLOGICAL SOCIETY, at 8.30.—Lantern Exhibition on the Moulting of the Arctic Fox: R. I. Pocock, F.R.S.—On the Moulting of the King's Penguin (*Aptenodytes pennanti*) in the Society's Gardens: D. Seth-Smith.—On the Presence of Two Ovaries in Certain British Birds, more especially the Falconidæ: T. E. Gunn.—Ontogenetical Transformations of the Bill in *Ardea cinerea*: Prof. P. P. Sushkin.—On some Collembola from India, Burma, and Ceylon, with a Catalogue of the Oriental Species of the Order: Dr. A. D. Imms.

WEDNESDAY, NOVEMBER 8.

FARADAY SOCIETY, at 8.—Address by Dr. E. G. Acheson.

GEOLOGICAL SOCIETY, at 8.—On the Interglacial Gravel-Beds of the Isle of Wight and the South of England, and the Conditions of their Formation: Prof. E. Hull, F.R.S.; The Gopeng Beds of Kinta, Federated Malay States: J. B. Scrivenor.

SOCIETY OF DYERS AND COLOURISTS, at 8.—Some Problems in the Dye n and Finishing of Silk Fabrics: W. P. Dreaper.

THURSDAY, NOVEMBER 9.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Modern High Voltag Power Transformers in Practice with special reference to a "T" Thre Unit System: W. T. Taylor.

THE CONCRETE INSTITUTE, at 8.—Presidential Address: Sir Hen Tanner, C.B.

ROYAL SOCIETY, at 4.30.—*Probable Papers*—The Spectrum of Boron: Si W. Crookes, O.M., For. Sec. R.S.—A Chemically-active Modification Nitrogen produced by the Electric Discharge. II.: Hon. R. J. Strut F.R.S.—Production of Solid Oxygen by the Evaporation of the Liquid Prof. Sir J. Dewar, F.R.S.—On the Gaseous Condensable Compound Explosive at Low Temperatures, produced from Carbon Disulphid Vapour by the Action of the Silent Electric Discharge. II.: Prof. Sir J Dewar, F.R.S., and Dr. H. O. Jones.—(1) Optical Dispersion: A Com parison of the Maxima of Absorption and Selective Reflection for certa Substances; (2) The Influence of the Solvent on the Position of Absor tion Bands in Solutions: Dr. T. H. Havelock.—An Experimental Invest gation of Gibbs's Thermodynamical Theory of Interfacial Concentration i the Case of an Air-water Interface: Prof. F. G. Donnan, F.R.S., an J. T. Barker.

THURSDAY, NOVEMBER 9, 1911.

TIDAL ACTION AND COSMOGONY.

The Tides and Kindred Phenomena in the Solar System. The substance of lectures delivered in 1897 at the Lowell Institute, Boston, Massachusetts, by Sir G. H. Darwin, K.C.B. Third edition. Pp. xxiv+437. (London: John Murray, 1911.) Price 7*s.* 6*d.* net.

THE first edition of this book appeared in 1898, and was reviewed in NATURE, vol. lix., p. 219. The work has since taken rank as a classic in its way, and has been translated into several languages. There is no need, therefore, to dwell at any length on its general character and purpose. It aims at giving, with as few technicalities as possible, a summary of the researches on tidal theory, and more especially on the theory of tidal evolution, which have been the principal occupation of the author's long scientific career. It would be misleading to describe it merely as a "popular" book, for it is a valuable guide even to experts who might otherwise be dismayed by the long and intricate calculations in which the original investigations necessarily abound. In this respect it may perhaps be compared with the celebrated "Exposition du Système du Monde" which Laplace added as a supplement to the detailed work of the "Mécanique Céleste." It is true that the subject-matter is in the present case more speculative, but the purpose is the same, and the execution not unworthy of the great exemplar.

In this third edition some additions and alterations have, however, been made which call for notice. These consist in part of supplementary notes to the earlier chapters, in which brief summaries are given of recent work bearing on the various topics. Thus at the end of the first chapter there is an interesting account of deep-sea tide gauges, with a tantalising indication of the valuable results which might be obtained if an extended and systematic use of such appliances were practicable. The appreciative account of Forel's early investigations of the "seiches" of the Lake of Geneva is appropriately supplemented by a reference to Chrystal's recent work on the Scottish lochs. The remarkable observations of Dr. Hecker on the lunar disturbance of gravity, which are the successful realisation of an interprise in which Sir G. Darwin himself led the way, are described with generous enthusiasm. In the absence of any authoritative account in English of these experiments, it is perhaps to be regretted that the description is not still more ample. Their value consists, of course, in the inferences which they justify as to the degree of rigidity of the earth. The other lines of evidence bearing on the same question, viz. those based on observations of the fortnightly tide, and on the free (Eulerian) nutation of the earth's axis, are also explained and discussed, the general conclusion being that the earth's surface yields, under the action of tidal or precessional force, about two-fifths as much as if it were absolutely devoid of rigidity. The more recent work of Love and Larmor, in which a greater degree of precision is given to the inferences which can be drawn from the respective lines of argument, was probably judged to be of too refined a character to admit of elementary treatment.

The views of the author as to the age of the earth, and the scale of geological time, have, as explained in this edition, undergone considerable modification. In 1898 the arguments of Lord Kelvin, which assigned a comparatively moderate age to the solid earth, were in the ascendant; but the rapid and startling succession of discoveries in radio-activity have undermined much of the reasoning based on such considerations as the output of energy from the sun and the secular cooling of the earth. Moreover, the researches of Strutt claim positively to demonstrate an enormous antiquity for certain rocks, far transcending the limits formerly accepted by physicists. On the other hand, an altogether independent estimate by Joly, based on a comparison of the amount of sodium in the ocean with the amount annually carried into it by rivers, would give to the existing ocean an age of about 100 million years at most, a figure which is on the scale of Kelvin's results. The discrepancy is at present unexplained, but we may note an interesting essay on the subject by Joly, in a recent number of the *Phil. Mag.* (September, 1911). Sir G. Darwin inclines, on a review of the whole evidence, to the belief that there is no assignable limit to the fund of time on which biologists may draw for the purpose of their evolutionary theories.

The last three chapters of the book are almost altogether new. The first of these is devoted to a general explanation of the theory of "figures of equilibrium" of rotating fluid, a classical problem with which the names of Maclaurin, Jacobi, Roche, Poincaré, and Darwin will always be associated. The theory of the stability of the various forms is of too technical a character to admit of really elementary treatment, but the summary will be welcome even to mathematicians, as a survey of a somewhat intricate subject. The succeeding chapter, one of the most fascinating in the book, gives a striking application of the theory to the phenomena of variable stars. The evolution of binary stars, a very attractive subject, is also considered, but the intricacy of such speculations is exemplified by the fact that a new source of instability, known as "gravitational instability," comes into play in the case of a gaseous mass. The concluding chapter treats of the nebular hypothesis of Laplace, and of the more important modifications of it which have been proposed by subsequent writers. In particular the "planetesimal" hypothesis of Chamberlin and Moulton, which was suggested by the observed prevalent spiral configuration of many nebulæ, is discussed at some length. Some speculations have an invincible attraction for the mind, but the critical reader will have an uneasy feeling that here at any rate he is making doubtful ventures into a mysterious region, far away from any secure dynamical base.

It would be wrong to end this notice without a word of admiration for the modesty and restraint which the author has shown in setting forth the results of speculations in the origin and development of which he has himself borne a predominant part.

The results of theoretical reasoning are always stated with scrupulous care, and their limitations clearly expressed, and no attempt is made to press conclusions based on idealised premises further than the case will warrant. A striking instance of this is furnished by the way in which, after developing his theory of the evolution of the earth-moon system with justifiable enthusiasm and evident faith, he takes care frankly to point out that other agencies must probably be sought to account for the origin of the satellites of the exterior planets and of the planets themselves.

H. L.

RECENT ADVANCES IN THE GENETICS OF PLANTS.

Einführung in die experimentelle Vererbungslehre By Prof. E. Baur. Pp. vi+293. (Berlin: Gebrüder Borntraeger, 1911.) Price 8.50 marks.

PROF. ERWIN BAUR is well known to students of genetics as a most successful investigator. The fifteen lectures included in the present volume were delivered as a course in Berlin, and they constitute an admirable text-book of the subject, which will do much to familiarise Continental biologists with the methods of Mendelian analysis and the deductions to which it has led. The coloured pictures are exceptionally good. No clearer or better illustrated account of the present state of knowledge of these matters could be desired.

Some years ago Prof. Baur began a series of researches into the nature of variegation in plants, without any special intention of investigating Mendelian phenomena, but, like so many others engaged on special problems, he soon found that a knowledge of heredity was indispensable to a proper understanding of his subject. The breeding experiments then instituted, though begun as a side-issue, have illuminated the whole field. His first success was obtained in a study of the golden-leaved Antirrhinum, which he proved to be a heterozygous form, possessing only one factor for greenness. Self-fertilised, it gives two yellows to one green, the missing term in the series being the homozygous albinos which perish on germination.

This led to a comprehensive examination of the inheritance of flower-colour in *A. majus*, a subject also studied by Miss Wheldale in this country. The series of types is very large, seeming at first sight almost continuous, and the analysis was exceptionally troublesome, but it is satisfactory to know that though working independently, both observers have arrived at practically the same conclusions as to the factorial composition of the several forms. In this book Antirrhinum is naturally taken as the typical example of the effects of combinations of long series of factors, and the reader who masters this example will have encountered most of the complications which ordinary Mendelian inheritance presents.

From this work on the varieties of a single species Baur has gone on to less familiar ground, and in this book he gives the first results of his experiments on the interrelation of forms which are quite distinct species in the systematic sense, especially *A. majus* and *A. molle*. The F_1 plants are fully fertile, and F_2 shows a long series of diverse types resulting from the recombination of segregating factors, but the analysis is still to be completed. One observation of extraordinary interest is announced, namely, that the self-sterility of *A. molle* is a recessive. This announcement must be regarded as preliminary, but if established, the discovery will constitute a striking advance. Self-sterility is one of the greatest paradoxes in nature. If it is true, as we are almost forced to believe, that a self-sterile plant can be fertilised by the pollen of *any* other individual but not by its own, then each individual is differentiated by virtue of its individuality, and there are as many classes as individuals. The notion once suggested by de Vries, which I also had formerly entertained, that there are in reality several *classes* of individuals and that probably fertilisation was inoperative only within each class, is negatived by such experiments as have been made by others and by myself (on a small scale in *Linaria vulgaris*). If self-fertility be a dominant, the main mystery is still unsolved, but we have a new fact of great consequence which may lead to a solution.

The most important chapters are those in which Baur describes his discoveries regarding the inheritance of the several forms of "Chimæra," the term Winkler has introduced to denote patchwork or mosaic individuals. In a variegated Pelargonium, for instance, the albino parts of the vegetative organs may be *sectorial* forming radiating patches of white, or *periclinal*, in which case the external layers of cells may be green and the internal white; or conversely the internal may be green and the external cells white. Baur has shown that the colour of the offspring, whether green or white, depends on the nature of the subepidermal layer of cells from which the parental germ-cells were derived. If in the periclinal chimæra the two peripheral layers of cells are green, the offspring (of self-fertilisation) are all green; if the peripheral layers are albino the offspring are all albino, and, of course, perish. If only the outer cell-layer is white the offspring are green. In either case the particoloured character does not reappear in the offspring. From the sectorial chimæras the inheritance is more complex, and much remains to be cleared up. This discovery of the significance of the subepidermal layer is one of very great importance, and we may anticipate that it will lead to remarkable extensions. It may not improbably lead to a reconsideration of the generally accepted doctrine that segregation takes place in gametogenesis.

Baur has applied these observations to the interpretation of the curious "graft-hybrids" between *Solanum nigrum* and the tomato, first made by Winkler. Some of these were obviously sectorial patchworks of the two species, but Baur suggested that of the others some were actual periclinal chimæras, in which a foundation of tomato was enclosed in one or in two cell-layers of *S. nigrum*, or conversely *S. nigrum* enclosed in an outer sheath of tomato tissue. This conclusion was at first strongly resisted by Winkler, but in a preliminary communication he has since announced the proof that it is correct, having himself by cytological investigation of the growing

points of the periclinal forms been able to prove that some of the layers have the chromosome numbers proper to *S. nigrum*, and others those of *Lycopersicum*. We can scarcely doubt that this remarkable series of observations will pass into the classics of biology.

On similar lines Baur proposes to elucidate the old problem of *Cytisus Adami* and *Crataego-mespilus*, the two traditional examples of "graft-hybrids." The former, for instance, is regarded as a Laburnum enclosed in a sheath of *C. purpureus*. On occasion, as when the exterior is wounded, the Laburnum can come out and develop. Baur's idea is doubtless a part of the truth, but I cannot clearly apply it to all the phenomena which *Adami* presents, especially to the sexual vagaries which it shows in this country at least. In it the *Adami* flowers have good pollen but no good ovules; the *purpureus* flowers have the female parts developed, but the anthers bad; while the *Laburnum* flowers are perfect and set seed in plenty. Nor do I clearly understand the origin of the *purpureus* branches. One can scarcely help suspecting that in the segregation by which these phenomena are produced there is some complex repulsion between the sex-factors and the factors for colour or form, comparable with the distinctions now known to exist between the genetic constitution of pollen and ovules of the same individual in several cases, *e.g.* Stocks and Petunia (Miss Saunders), or Œnothera (de Vries).

The only point in this excellent book which calls for criticism is, in my judgment, the rather crude representation of segregation as effected by chromosomes. These pictures will live in the memory of the reader, and tend to limit his imagination of the possibilities more closely than the known facts at present warrant.

W. Bateson.

THE RUSTING OF IRON.

The Corrosion of Iron and Steel. By Dr. J. Newton Friend. Pp. xiv+300. (London: Longmans, Green, and Co., 1911.) Price 6*s.* net.

THE author gives a concise account of all the important work that has been carried out in connection with investigations relating to the causes of corrosion of iron and steel. The book is a model of its kind, since the references to original contributions to knowledge are exhaustive and will serve to direct the investigator to the literature of that branch of the subject in which he is specially interested. After dealing with the action of air, of water and of steam on iron, the various theories which have been advanced to explain corrosion are discussed, and the conclusion is drawn that "the most recent experimental results are entirely in favour of the acid theory of corrosion."

The action of acids and of alkalis, and the influence of solutions of salts of various kinds on iron are next considered, and a short chapter is then devoted to the action of oils on the metal. In dealing with the subject of the passivity of iron the author has failed to make clear the fact that the immersion of the metal in chromic acid must necessarily bring about the removal by oxidation of such impurities as manganese sulphide, which exist on the surface, and form acids on exposure to moist air. The metal by such treatment must in consequence be rendered more resistant to corrosion irrespective of any question of passivity. Nor is attention directed to the fact that the surface of iron immersed in chromic acid must necessarily remain bright whenever the acid is sufficiently concentrated to dissolve any rust which might be formed, and in this connection it may be noted that ferric hydroxide dissolves readily even in dilute solutions of chromic acid. Moreover, H. B. Baker and others have clearly shown that whatever properties are given to iron by immersion in dilute chromic acid immunity from rusting is not one of them, and it is extremely doubtful if previous immersion in chromic acid of any strength is a protection against atmospheric oxidation of iron.

The last three chapters of the book deal respectively with the influence of chemical composition on the corrodibility of iron, with electrical effects and with the relative rate of corrosion of iron and steel. The first of these might with advantage have been considered at an earlier stage—the author states that it is of paramount importance—since an explanation of that troublesome form of corrosion known as pitting in water-tube and other boilers must be sought mainly in the chemical composition of the iron of which they are made. The chapter on electrical action opens with the unfortunate statement that, "as is well known, when an electric current passes through water, the latter is readily split up into its constituent elements, oxygen and hydrogen." This erroneous inclusion of water amongst electrolytes may produce confusion in the minds of some readers, and is greatly to be regretted.

The book is well illustrated throughout, and will appeal to the general reader of scientific literature since it contains matters of interest apart from technical detail. For instance, an account is given of the Iron Pillar of Delhi, dating from 912 B.C., as an example of iron which has for centuries resisted atmospheric attack. There is, however, no record of the very rapid corrosion of the steel pipe line which conveys water from Mundaring to the Kalgoorlie Goldfield in Western Australia, and represents an outlay of upwards of 3,000,000*l.* sterling. Some account of the reports presented to the Government of Western Australia on this matter might with advantage have been cited, and the suggested treatment of the water by deaëration and liming, involving an expenditure for machinery of 187,000*l.*, discussed.

G. T. M.

ASPECTS OF THE EARTH'S STORY.

The Changeful Earth: an Introduction to the Record of the Rocks. (Readable Books in Natural Knowledge.) By Prof. G. A. J. Cole. Pp. x+223. (London: Macmillan and Co., Ltd., 1911.) Price 1*s.* 6*d.*

IT is refreshing to turn from the ordinary text-books of science—useful and necessary as such works undoubtedly are—to a booklet like that now before us. Science manuals in their efforts after inclusion and compression, in order to meet the wants of examination candidates, tend to become dogmatic in their

teachings, and the student is led to rely on the authority of the teacher rather than on any process of reasoning; of such works we must sadly confess "the trail of the examiner is over them all."

But for those who would learn to love geology for itself, Prof. Cole has supplied a charming, and at the same time trustworthy, introduction to the science. He has wisely adopted what may be called "the recapitulation method" of teaching, that is to say, he introduces new facts and ideas in the order and by the reasonings through which they were originally discovered, and by which the present position of the science has been gradually attained; knowledge is made to grow in the individual mind along the same lines as it can be shown to have done, though far more slowly, in the history of our race. It is needless to add that such a mode of presentation must be, to a great extent, biographical.

After some preliminary considerations, the author shows, in the first place, the steps by which William Smith, "the father of English geology," was led to his epoch-making discoveries of a stratigraphical succession, based on the evidence of fossils. Then turning from southern England to the Paris Basin, the labours of Lamarck and Deshayes, of Cuvier and Brongniart are indicated as affording useful aids to Charles Lyell in proving that, in the latest formed geological deposits, life-forms gradually replaced one another, thus lending support to the more general conclusion that the same continuity becomes manifest, as we trace the succession to the remotest past.

In succeeding chapters, the effects of running water, as taught by Hutton, and of moving ice, as shown by Agassiz, are well described, with illustrations drawn from the author's own observations and those of his contemporaries. "The Throat of a Volcano," "The Giant's Causeway," "The Making of Mountains," and "A Year of Earth Storms," are the headings of other chapters of this entertaining and instructive book, in which the labours of the pioneers of research are in all cases described with warm sympathy and just discrimination. The numerous illustrations of the book are, for the most part, from photographs taken by the author, and if any further evidence were needed that his descriptions are based on actual visits to the districts, it will be found in many a picturesque phrase. The hardest working college student, no less than the general reader, will find it an advantage to peruse this bright little book, for he can scarcely fail to catch some sparks of the enthusiasm of the author, which glows on every page.

J. W. J.

BANTU MYSTICISM.

Notes on West African Categories. By R. E. Dennett. Pp. xi+68. (London: Macmillan and Co., Ltd., 1911.) Price 1s. net.

IN this small book or enlarged pamphlet, Mr. R. E. Dennett recurs to his theories regarding formulæ, religious categories, and transcendental symbolism which he has believed himself able to trace in the employment of prefixes and word roots, more especially amongst the Bavili, a Congolese tribe of the Loango coast, and also in a lesser degree amongst the Yoruba and Bini peoples of the Niger Delta.

Mr. Dennett cannot fail to write interestingly on any African subject with which he is personally acquainted, since whether one agrees or not with his theories one is certain to find new and true facts in his compilations. But the reviewer is still quite unable to endorse from his own experience the probability that the Bavili (more especially) could have developed such an elaborate mathematical cosmogony and theology as Mr. Dennett places to their credit, and bases on the forms of their prefixes and of their word roots. As happens all too often, to the sorrow of the universal student of Bantu languages, Mr. Dennett has made a study of one particular Bantu dialect and deduces from his study theories which fall to pieces directly one compares that dialect with another of the same group, or one Bantu language with another. He strives to show that in the minds of this particular coast Congo people certain great categories of thought exist. For instance, he would devise a category which should contain four visible and four invisible parts, or another which should range from 0 to 9, and should correspond with certain classes of Bantu prefixes; and again others which correspond with ideas of God, the procreation of the human species, abstract qualities, such as receptivity, originality, order, manner, action, quality, &c.

To anyone who knows the negro as well as the present reviewer may claim to do, much of this appears impossibly fantastic and unreal; and when such theories are based on a misunderstanding (sometimes) of the original form and purport of prefixes in tongues closely related to the Bavili and similar correspondence of word roots, they reduce one to something like despair; for Mr. Dennett, who, as regards his recorded facts, is often so accurate and so helpful to students of Africa, wastes his time and thoughts on prolix theories which seem to be devoid of any scientific foundation. If, as he says in the beginning of his book, he has won over that notable student of the Bantu tongues, Miss Alice Werner, to a belief in, or even a toleration of, his theories given in "At the Back of the Black Man's Mind" and in the present pamphlet, it can only be deeply regretted that both of them should be following a will-o'-the-wisp. This opinion, most regretfully written, does not prevent "Notes on West African Categories" from being a work of considerable interest, and containing many new observations of value which seem to the reviewer perfectly sound as statements of fact.

THE VOICE OF LYELL.

The Student's Lyell: the Principles and Methods of Geology, as applied to the Investigation of the Past History of the Earth and its Inhabitants, with Historical Introduction. Edited by Prof. J. W. Judd, C.B., F.R.S. Second edition, revised and enlarged. Pp. 645. (London: J. Murray, 1911.) Price 7s. 6d. net.

IT is most fitting that the revision of Lyell's "Students' Elements of Geology" should be again carried out by Prof. J. W. Judd, who brings

to his work such intimate knowledge of Lyell himself, and such broad experience as a geological teacher. Prof. Judd's pupils in many lands will find again in this volume those stimulating memories of Lyell's life and work which they received from their own master in the Royal School of Mines. The "historical introduction" to the present edition, occupying fifty-six pages, is not only a welcome essay on the influence exerted by the doctrine of causes now in action, but also a defence (pp 49–52) of Lyell from the charge of excessive uniformitarianism. Those who have not made themselves acquainted, as Prof. Judd has done, with the extravagant speculations of geological divines and of laymen aspiring to divinity, before the days when the influence of Hutton, von Hoff, and Lyell came to be generally appreciated, can scarcely realise the sense of calm and order that was brought by these authors into a world of controversy. Charles Darwin's admiration for the "Principles of Geology" would alone assure us of Lyell's position as a thinker; and now, in turning the pages of this new issue of his admirable text-book, we are again reminded that here was a man who wrote because, and only because, the spirit moved him.

The refined woodcuts are here that we first knew in 1871. Drawings of such modernities as radiolarian ooze and thin sections of rocks have been introduced, and toothed birds and other American vertebrates are illustrated; but the view of geology remains, in the hands of so sympathetic an editor, essentially that of Lyell in his habit as he lived. We look back into the past from our experience of the present; a pleasant emphasis is laid upon the Tertiary strata throughout Europe; and the work reminds us in so many places of the history of geological thought that it still stands apart from any other text-book.

Supplementary notes have been added (pp. 601 to 610) directing attention to many recent discoveries, and these, in so limited a compass, naturally provide food for thought rather than a complete exposition. We miss a reference to the older glacial epochs; the stratigraphical breaks indicated in the diagram on p. 441 surely exaggerate enormously the imperfection of the European record; and many geologists would like to expand the modest view of contact-metamorphism stated on p. 553. It is easy to comment on details where so wide a range of subjects has been dealt with. The essential feature is that the editor has handed on to us undimmed the lantern lit by Lyell.

G. A. J. C.

MODERN KNOWLEDGE HANDBOOKS.

(1) *Polar Exploration.* By Dr. W. S. Bruce. Pp. 256.
(2) *The Evolution of Plants.* By Dr. D. H. Scott, F.R.S. Pp. 256.
(3) *Modern Geography.* By Dr. M. I. Newbigin. Pp. 256.
(Home University Library of Modern Knowledge.) (London: Williams and Norgate, n.d.) Price 1s. net each.

THE three volumes the titles of which are given above belong to the Home University Library of Modern Knowledge, published by Messrs. Williams and Norgate under the editorship of Prof. Murray, Mr. Herbert Fisher, and Prof. J. Arthur Thomson. Each is intended to be a concise handbook to the subject with which it deals, and by an acknowledged authority. The object of the series is to place within everyone's reach, at the lowest possible price, authoritative information on any branch of history, science, art, literature, philosophy, or religion with which he desires to become acquainted. Ten volumes will be issued each year. The first on our list, "Polar Exploration," by Dr. Bruce, is what the author has termed a "traveller's sample" of the Arctic and Antarctic warehouses. No one is more competent to present their contents than one who has personally sampled as he has done, more than once, both polar regions, and has besides learned much in regard to them from personal conversations and correspondence during the past twenty years with living polar explorers, including the veteran Sir Joseph Hooker, to whom the volume is dedicated. The personal note predominates, as it needs must, and those parts visited by the author are dealt with in greater detail than those which he has not had an opportunity of visiting. The aspects of the subject dealt with in the present volume are the astronomical features of the polar regions; the ice, both land and sea, its coloration and that of snow; the vegetation, the animal life and the physics of these regions; their meteorology, magnetism, aurora, and tides, with a final chapter on the aims and objects of modern polar exploration. Not the least important addition to the physics of the southern seas made by the Scottish national Antarctic expedition was the discovery of the existence of a long "rise" extending in a curve from Madagascar *via* Bouvet Island, the Sandwich group, the South Orkneys, Graham Land, and the Falklands to South America. "Thus Antarctica, South America, and Madagascar and probably South Africa become connected with one another in a most direct manner by this rise." The volume smacks of a Stevensonian voyage.

(2) "The Evolution of Plants" is a masterly *résumé* of this extremely difficult subject by one of our highest authorities, himself a leading investigator in palæobotany. Dr. Scott's object in this book is to try to trace historically the course which the evolution of plants has actually followed, confining himself to those groups for which the evidence is most satisfactory. The questions here considered are: the evolution of true-flowering plants; that of the seed-plants generally; and, thirdly, that of the great groups of the higher cryptogams, or spore-plants, the ferns, the club mosses, the horsetails and sphenophylls. Dr. Scott's work "needs no bush."

(3) Dr. Marion Newbigin dates the commencement of "modern geography" only from 1859, the year when the celebrated geographers Humboldt and Ritter died and Darwin's "Origin" appeared. The doctrine of evolution has had an enormous effect on geographical science, and its development has been so great that to give a complete survey of the subject would be impossible. Her volume, "Modern Geography," therefore, suggests only some of the

lines along which research is proceeding most actively at the present time, special stress being laid upon those aspects of the subject which are not as yet fully treated in the smaller text-books.

The first four chapters deal with a general survey of the earth's surface, its mountains and ocean depths, the formation of its hills and valleys due to atmospheric agents, running water and ice, and the effects of climate on the distribution of other phenomena on the surface of the globe. In the successive chapters the author describes the three chief zones of vegetation, the Mediterranean scrub land, the temperate forest zone, and the steppe or pasture land, and that as each of these is determined by climate, each again has special types of cultivated plants and domesticated animals.

"It is interesting to note," adds the author, "what cannot be a pure coincidence [and yet may it not be so?], that in Europe three races of men exist, which show a certain rough correspondence to the three zones of vegetation. The Mediterranean type of vegetation and climate is associated" with the Mediterranean race. . . . "The characteristic inhabitants of the temperate forest region of Europe are members of the race called Teutonic or Nordic . . . the steppe and pasture lands . . . tend to be occupied by a third race . . . to which the . . . name of Alpine has been given."

The penultimate chapter is devoted to the races of Europe and their origin, and the last to the distribution of minerals and the localisation of industries and of towns. "Modern Geography" is a suggestive book.

Although the space at our disposal precludes a detailed notice of these volumes, we can warmly and conscientiously recommend them to those interested in the subjects with which they deal. All three are provided with full indexes, and "The Evolution of Plants" has besides an excellent bibliography of the most important works on palæobotany.

OUR BOOK SHELF.

Medical Science of To-day: a Popular Account of the More Recent Developments in Medicine and Surgery. By Dr. Willmott Evans. Pp. 324. (London: Seeley, Service, and Co., Ltd., 1912.) Price 5*s.* net.

THIS is a very delightful book. None of the natural sciences has greater wonders to tell than medical science; none touches more nearly our admiration of good work slowly brought to success. Dr. Willmott Evans is an excellent interpreter; he understands the art of freeing the wonder of the discovery itself from the wrappings of long words put round it by the doctors; he makes the reader feel the intense human significance of the many facts on which the present fabric of medicine and surgery is founded and built; and his book ought to be very widely read and remembered.

Of course, with such an "imperial theme," it was not possible for him to say all that ought to be said. The embarrassment of riches left him only a paragraph or two for methods each deserving a chapter. But he ought to have found room to say more about the tremendous influence of the experimental method in medical science. For instance, his mention of brain-surgery does not do justice to the experimental study of cerebral localisation; and the same fault occurs in his chapter on organo-therapy. And, of course, there are omissions of less importance; thus he speaks of yellow fever without naming Walte Reed, and he describes myxœdema without givin photographs of cases before and after thyroid treat ment. He might with advantage have left out th chapters or subchapters on patent medicines, idiosyn crasies, and malingering; the chapters on legal medi cine also want thinning.

The one grave defect in the book is the over shadowing of methods by results; he shows us th thing made, not the thing in the making. Still, h has written a book which is excellent reading; h plainly has enjoyed writing it, and it gives a faithfu and valuable account of the modern science and ar of medicine, surgery, and preventive medicine.

Climatic Control. By L. C. W. Bonacina. Pp. viii + 167. (London: A. and C. Black, 1911.) Price 2*s.*

WORKS on climatology and articles in meteorologica text-books treating of that subject abound in variou forms, but that there is still room for others dealin with different aspects of this important question i shown by the interesting and useful little volume nov under review. It is published as one of the series o "Black's School Geography," and, being intende primarily for British students, prominence is give to the climate of this country, but that of other "well known lands," selected as representative of the variou zones and regions, is considered at some length.

In an instructive chapter on the general principle of climatology, the factors which produce variation in different parts of the world—*e.g.* latitude, altitude prevailing winds, &c.—are separately discussed, an this is followed by chapters (1) on the types of lan and the effect of the prime elements of light, heat an moisture, the distribution of vegetation being take as a rough criterion of the climatic variations; and (the influence of climate upon man. The whole c these various aspects are treated in a manner tha cannot fail to attract the attention of students, an to induce them to pursue the subject further. Th last chapter deals with meteorology and is in tended for more advanced students. This chapte like those preceding it, exhibits an intimat knowledge of the subject, and we regret that i was found necessary, for lack of space, to omit ques tions relating to atmospheric electricity—*e.g.* thunde storms, &c.—and to optical phenomena.

The effect of the rotation of the earth on the ci culation of the air and on the behaviour of cyclone and anticyclones and many other questions sometime presenting difficulty to students are clearly explaine A few well-chosen synoptic charts, recently publishe by the Meteorological Office, are added to explai some of the principal types of weather.

An Introduction to Chemical Theory. By Dr. A Scott, F.R.S. Second edition. Pp. viii + 27 (London: A. and C. Black, 1911.) Price 5*s.* net.

THE first edition of this book was published twent years ago, just as the "new" physical chemistry wa flowing into this country and gaining admission t lecture courses and text-books. It was in a way th last of its race, and it still retains in the new editio a marked mid-Victorian flavour. This is not said i disparagement; indeed, the restraint shown by th author on the more speculative side of theoretica chemistry is a reminder of what in some respects wer better days.

The distinction between chemical philosophy general chemistry, and physical chemistry has becom very vague, but Dr. Scott's book may be describe as dealing rather with chemical philosophy tha physical chemistry, and in that character it has som distinctive features which may give it a place in th

student's armoury. Such, for example, are the two chapters on the classification of compounds.

The treatment throughout is simple and lucid, and there is nothing that is likely to puzzle or mystify a reader. The contents will give him a good, useful store of information relating to the theoretical side of chemistry, though it will be meagre on the topics which have come to the front during the last twenty years, and to which, in a mere revision, it has scarcely been possible to do justice. In some cases the faults pass beyond those of omission, as in the confusion between dissociation and hydrolysis on p. 172, the account of "palladium hydride" on p. 171 and the definition of cryohydrates on p. 255. A. S.

Marvels of the Universe. A Popular Work on the Marvels of the Heavens, the Earth, Plant Life, Animal Life, the Mighty Deep. By various authors. In about twenty-four fortnightly parts. Part i., pp. 48. Part ii., pp. 48. (London: Hutchinson and Co., n.d.) Price 7d. net each part.

OF the attractiveness of this serial publication it would be difficult to write too highly. Each part contains four full-page illustrations in colour, remarkable alike for their beauty and accuracy, and a profusion of excellent pictures in black and white, most of which are from photographs.

The contributors are well-qualified authorities on the subjects they have undertaken, and what they have written is appropriate to the work. The selection of topics has been guided entirely by what is likely to arrest the attention of the non-scientific general reader, with the result that instead of an orderly introduction to science, we have a series of short, bright views of some of the wonders of nature, arranged in no logical sequence, but partaking of the character of a scientific scrap-book, using the term to express disjunctiveness rather than depreciation.

Unrelated as the articles are, they may serve a very useful purpose and succeed in attracting readers to the more serious study of some science in which they will be led themselves to observe and record what is happening in the world around them, as well as to take an interest in the explorations of others.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Scientific Misappropriation of Scientific Terms.

WHILE fully sympathising with Prof. Gregory in his condemnation of the scientific misappropriation of popular terms, and, indeed, objecting to the scientific *appropriation* of such terms where it would be better to employ a universally intelligible technical language, still, it seems to me that even more deserving of condemnation is the misappropriation by one group of scientific workers of the scientific terms used by another group. This procedure is the more objectionable when the two groups of workers are in adjoining fields. It does not greatly hurt anyone that an astronomer should mean by an "asteroid" something quite different from that which a zoologist means; but it does matter when one biologist uses a term in a different sense from another biologist.

Of late years some of us have felt driven to protest against Prof. H. de Vries's use of the term "mutation" in a sense differing in an apparently trivial, yet philosophically important, way from the use of the term by its original inventor—the palæontologist Waagen. Now we find the followers of Prof. de Vries, notably Prof. Johanssen, robbing the systematic biologists of their term "genotype." First proposed by Prof. C. Schuchert in 1897, this term has come into very general use to denote the type-species of a genus. There has been in the past so much confusion between the different senses of the word "type," and this confusion has given rise to so much regrettable confusion of thought, that this latest malappropriation should only need pointing out to be at once stopped. Unfortunately, this simple action has not had the desired effect, and therefore I am impelled to make a protest in your widely read pages. F. A. BATHER.

Wimbledon, November 2.

The Electro-vegetometer.

EXPERIMENTS with electricity as a stimulant to plant growth were made with alleged success 165 years ago, when Mr. Maimbray, of Edinburgh, electrified two myrtles throughout October, 1746, for several hours a day, with the consequence that next summer they blossomed sooner than their neighbours (Priestley's "History of Electricity," part viii., sec. 4).

Shortly after this the Abbé Nollet made similar experiments with electrified seeds in pots, and claimed equally successful results. M. Achard, of Berlin, and other independent observers confirmed the experiments; and the beneficial effect of electrification on plant life was almost an accepted discovery when a Dr. Ingenhousz, after exhaustive experiments, completely refuted all the conclusions hitherto arrived at, and proved that the only effect of electrification was to hinder plant life!

Dr. Carmoy and the Abbé Ormoy later resumed the investigation, and testified to favourable results.

Next the Abbé Berthelon reconciled these divergent conclusions by announcing that electricity in a moderate application was beneficial, but could be applied in excess with harmful results; and he advocated as the safest method the utilisation of atmospheric electricity, which he said rarely rose to a strength injurious to the most delicate plant. He published a suggestion, recently credited by Sir William Ramsay as a new and ingenious theory of Sir Oliver Lodge's, that the pointed leaves of plants acted as conductors of atmospheric electricity, and were an important factor in the prolific vegetation of forests.

The Abbé Berthelon, who utilised both natural and artificial electrification, devised what he called the "electro-vegetometer," which consisted of an insulated series of sharp iron points projecting vertically upwards at a mast-head and connected by chains with similar iron points pointing downwards just over the plants to be experimented on. He states that "the happiest effects were perceived, viz. different plants, herbs, and fruits in greater forwardness than usual, more multiplied, and of better quality."

Until lately all these alleged successes were supposed to have been imaginary; and the question is, Will the recent experiments prove that there was more in the earlier ones than has been supposed, or will the present trials turn out to be, with their predecessors, further examples of myths of science, like the Blondlot rays and Mrs. Somerville's supposed discovery of a magnetising power in solar light? CHARLES E. BENHAM.

Colchester, November 5.

November Meteor-showers.

THE early part of November does not present anything very noteworthy as regards meteoric phenomena, which may be said to begin about November 9, the following being the principal meteor-showers of the month:—

Epoch November 9, 6h. (G.M.T.), first order of magnitude. Principal maximum, November 11, 0h. 30m.; secondary maxima, November 9, 11h. 50m., and November 10, 10h. 40m.

Epoch November 10, 15h. 30m., twenty-second order of magnitude. Principal maximum, November 11, 11h. 30m.; secondary maxima, November 11, 19h. 20m., and November 12, 7h. 40m.

Epoch November 13, 16h., thirtieth order of magnitude. Principal maximum, November 14, 22h. 50m.; secondary maxima, November 15, 9h. 30m., and November 16, 13h. 15m. and 17h. 30m.

Epoch November 16, 10h., thirteenth order of magnitude. Principal maximum, November 15, 21h. 10m.; secondary maximum, November 15, 7h. 15m.

Epoch November 17, 3h. 30m., tenth order of magnitude. Principal maximum, November 17, 17h. 25m.; secondary maxima, November 17, 23h. 30m., and November 18, 5h. 5m.

Epoch November 17, 15h. 30m., approximately sixth order of magnitude. Principal maximum, November 19, 12h. 55m.; secondary maxima, November 18, 15h. 15m., and November 19, 22h. 10m.

Epoch November 24, 2h. 30m., approximately fourth order of magnitude. Principal maximum, November 23, 5h. 30m.; secondary maxima, November 22, 15h. 20m. and 18h. 20m.

Epoch November 25, 4h. 40m., eighteenth order of magnitude. Principal maximum, November 24, 2h. 35m.; secondary maxima, November 24, 12h. 40m. and 23h. 10m.

It is significant that, of the eight principal epochs of the month, no fewer than six fall due during the period of November 9–20. This, therefore, is the part of the month richest in meteoric events. The two remaining epochs of November 24–25, though nominally strong, do not rank in importance with the foregoing six.

Of these six there are three that call for special mention. The first, commencing on November 9, has the highest meteoric intensity of the month; but the epoch of November 17, 3h. 30m., may prove to be the most interesting, as it bears a certain resemblance to the epoch of November 15, 1905, and in the writer's opinion is liable to be associated with auroral phenomena. The small intermediate epoch of November 13, 16h., is the only one that places maxima between 12h. and 18h. on any of the three nights November 14–16, two of its secondary maxima becoming due between these hours on the night of November 16. The general Leonid maximum will therefore probably be best observed on the night of November 16, but late members of this well-known star shower are likely to be strongly in evidence also on the following night.

JOHN R. HENRY.

2 Belgrave Villas, Rathmines, Dublin, November 6.

Tick (Ixodoidea) Generic Names to be included in the "Official List of Zoological Names."

(1) THE international committee invited by the secretary of the International Commission on Zoological Nomenclature to make a detailed study of the nomenclature of ticks (Ixodoidea), and consisting of the following specialists in this group, W. Dönitz (Berlin), Albert Hassall (Washington), L. G. Neumann (Toulouse), G. H. F. Nuttall (Cambridge), and Cecil Warburton (London), has submitted its first report.

(2) Said committee unanimously agrees that the following eight generic names are the correct names for the genera in question, and that the correct genotypes, according to the international rules of zoological nomenclature, are the species cited:—

Amblyomma Koch, 1844a, 223–231, type *cajennense* Fabricius, 1787.

Argas Latreille, 1796a, 178, type *reflexus* Fabricius, 1794.

Dermacentor Koch, 1844a, 235–237, type *reticulatus* Fabricius, 1794.

Haemaphysalis Koch, 1844a, 237, type *concinna* Koch.

Hyalomma Koch, 1844a, 220–223, type *aegyptium* Linnæus.

Ixodes Latreille, 1796a, 179, type *ricinus* Linnæus.

Rhipicentor Nuttall and Warburton, 1908, 398, type *bicornis* Nuttall and Warburton.

Rhipicephalus Koch, 1844a, 238, 239, type *sanguineus* Latreille.

(3) Notice is hereby given that the undersigned will wait until May 1, 1912, for any zoologist to raise any objection to any part of the report of the special committee. If no valid point is raised by the date mentioned, the undersigned will transmit the list to the International Commission with the motion that these names be incorporated in the "Official List of Zoological Names" provided for by the last International Zoological Congress.

All correspondence on this subject should be directed to

C. W. STILES.

Localising Minute Leaks in Vacuum Apparatus.

IN view of the fact that in many branches of physical research there has arisen of late years the necessity for complicated apparatus to be kept at a high state of exhaustion, it may interest your readers to hear of a simple method of localising minute leaks.

In the case of leaks in "all glass" apparatus, I have for many years used with success Goldstein's spark method. This consists in disconnecting the kathode lead from the apparatus, putting in a small alternate spark-gap, and exploring over the suspected joints with the loose lead until a brilliant discharge to the inside of the apparatus indicates the position of the leak. The objections to this method are that if parts of the glass are very thin a hole may be made where none previously existed; it obviously cannot be used near a terminal, or at all with a "wax" joint.

An apparatus of mine involving seven distinct and complex sealing-wax joints recently developed a microscopic leak of about 1/100 mm. per hour. Being faced with the alternative of pulling the whole apparatus down and remaking every joint, it occurred to me that the extremely sensitive nature of the discharge in air to change its colour when in the presence of carbon compounds (it is, in fact, by the change from the grey of CO to the crimson of N that leaks are generally first seen) might be used with advantage. I therefore wiped each joint over with a small pad of cotton-wool soaked in petrol, keeping the discharge going meanwhile, and the instant the real offender was reached—a "metal-wax-glass" joint in this case—the discharge turned abruptly from red to blue. The method seems extraordinarily delicate, and should be applicable to all cases of air leak so long as the latter is not so large as to prevent the discharge passing.

F. W. ASTON.

Cavendish Laboratory, Cambridge, October 31.

Multiple Rainbows.

ON Tuesday morning last, October 31, a succession of rainbows of extraordinary brilliance was visible here. The most brilliant appeared at 8.45 a.m., and lasted about five minutes.

The sun was shining brilliantly, and the atmosphere to the east was remarkably clear, while the rain-storms came up from the Bristol Channel, eight miles to the west. At 8.45 a.m. six rainbows were visible, *three* inside the main bow and very close to it, the colours being in the same order as those on the main bow, and two outside, the colours of the first being in reversed order, while the second was faint, and nearly white. Four of the rainbows were quite perfect, but the innermost of the three internal bows was partly broken, only three-quarters being visible. About one-third of the extreme outer bow was visible.

Dangerous Mixtures.

I SHOULD like to direct attention to the dangerous nature of a mixture consisting of magnesium powder and silver nitrate.

When a small quantity (2 to 3 grams) of magnesium powder is mixed with an equal bulk of powdered silver nitrate in a metal dish, and then from the end of a long glass rod a drop of water is allowed to fall on the mixture, a slight explosion occurs, accompanied by a vivid flash.

The unexpected violence of this reaction led to serious burns in my own case.

Mercuric nitrate when substituted for silver nitrate also reacts vigorously with magnesium powder under the same conditions, brown fumes, but no flash, being produced. With barium nitrate the action is slight, heating only appearing to take place.

HAROLD CALAM.

The University, Leeds, October 27.

THE SOLAR PHYSICS OBSERVATORY.

In last week's NATURE we gave the terms of reference of the departmental committee appointed to consider alternative schemes for transferring this observatory to Fosterdown (Caterham) or to Cambridge.

We are informed that the Treasury has forwarded the report of the committee on this subject to Cambridge, and that it is being considered there; so far we believe no communication has been made to the Solar Physics Committee, the body appointed more than twenty years ago to advise the Government in such matters.

We may summarise now the action taken by the committee and the Board of Education as already recorded in NATURE during the last five years.

(1) In 1906 the Board informed the committee that the land on which the Observatory is situate was required for the Science Museum, and requested them to make inquiries regarding a new site.

(2) The committee formulated the conditions to be fulfilled, and, after inspection of all available Government land in 1907, fixed upon Fosterdown as fully satisfying all the conditions.

(3) The Treasury, in full knowledge of this, proposed Cambridge as an alternative site, although it fulfilled none of the required conditions.

(4) The committee pointed out that this raised questions concerning administration, &c., and asked for more information, and suggested a committee to obtain it, consisting of representatives of the Treasury, the Board of Education, the Solar Physics Observatory, and the Meteorological Office, to consider fully the question of the alternative sites in all its bearing.

(5) Without any communication with the committee, the Treasury requested the War Office to sell the Fosterdown site.

(6) As a result of a memorial to the Prime Minister this proceeding was at once stopped.

(7) The Treasury, thus compelled to hold an inquiry, instead of such a body as that suggested by the committee, with knowledge of the work done in the Solar Physics Observatory and the questions of administration involved, appointed a committee consisting of three fellows of a Cambridge college and the holder of an honorary degree of the University.

(8) The majority of this committee has selected Cambridge as the future site for the observatory.

THE SITES CONTRASTED.

Up to the present time the actual conditions of the two sites as observing stations have not been published, so some trouble has been taken to prepare maps to indicate their relative efficiency.

To illustrate this the accompanying two charts are here reproduced, the first (Fig. 1) representing the Cambridge site and its neighbourhood, and the second (Fig. 2) that at Fosterdown. A study of these two charts will at once demonstrate the respective values of the positions for an observatory to be erected *for all time.*

It is well recognised that the best observations of the sun are made soon after the sun has risen, so that it is essential that the eastern horizon as seen from the observatory should be open and free from a smoky atmosphere. In the plans, lines showing the directions of the sun at sunrise at both the summer and winter solstices have been indicated in order to point out the kind of country (town or fields) over which these observations in the east should be made.

The following comparisons show how the conditions laid down by the Solar Physics Committee are fulfilled or the reverse by the two sites in question:—

"The observatory should be at an elevation of not less than 250 feet, if practicable."

FIG. 1.—Cambridge. The selected site, 70 feet above sea-level, is at the centre of the half-mile and mile circles, and lies 45 feet above the river flats to the eastward. The lines SS and WS represent the directions of sunrise at the summer and winter solstices respectively. Solar observations, which have to be made soon after sunrise, must therefore be made through smoky and misty atmosphere due to the town and river valley respectively.

Cambridge.—75 feet.

Fosterdown.—800 feet.

"In any case it should not be in a smoke area."

Cambridge.—Near a smoke area, namely, the town of Cambridge, and this lies to the east and south-east of the site, and is extending westwards, *i.e.* in the direction of the observatory.

Fosterdown.—No smoke area.

"It should be away from river valley mists and not upon a clay soil (chalk or gravel would be quite satisfactory)."

Cambridge.—River mists and flooded areas by the River Cam—to the east and south-east of the site.

Fosterdown.—No river near the site.

"In the configuration of the ground the important considerations are that the site should not be exposed

to violent winds, and that it should afford as clear horizon as possible, especially to east, south, and west."

Cambridge.—The extension of Cambridge in the direction of the site is increasing, and there is no *natural* guarantee to prevent buildings (which mean smoke) from being erected on any of the sides of the observatory site.

Fosterdown.—The configuration of the site is such that the horizons will be open and clear *for all time*.

It may be further stated that while at Cambridge a main road passes close to the site of the observatory and traffic along it even now shakes the ground, at Fosterdown no such road can be constructed, and therefore no such earth tremors need be feared.

It will therefore be seen that for the work's sake it would be much better to place the observatory in the best position at once, even if it may cost a few hundred pounds more, than to locate it at Cambridge,

At the same time that this report was presented to both Houses of Parliament the third report of the committee appointed to advise the Government on this matter, called the Solar Physics Committee, was also presented. This covers the period 1889–1909 (two previous reports presented in 1882 and 1889 dealt with the period from 1879, when the observatory was founded by the Government).

A perusal of this report enables us to see what work has been done in the past. The report of the departmental committee deals with proposals for its future.

The situation is as follows:—

A Government observatory, more than thirty years old, has to be moved from its present position because the land is wanted for the buildings of the new Science Museum.

When the question of the change of site of the observatory was first brought up a thorough investigation was made by the Solar Physics Committee. They formulated the conditions which had to be secured, and proceeded to search for a suitable site. The conditions which they laid down are given in the departmental committee's report (p. 4)—roughly, the site should be as high as possible, to

FIG. 2.—Fosterdown. The selected site, 800 feet above sea-level, is at the centre of the half-mile and mile circles, and lies 100 feet above all the neighbouring country with the exception of the small 800-foot area to the north of east, which is on the same level as the site. The lines SS and WS are the directions of sunrise at the summer and winter solstices. The figure shows the open and clear nature of the horizon in all directions.

where at the present time the observing conditions are not good; where year by year they will be getting worse; and where in a short period they will become intolerable for similar reasons which make the present site at Kensington undesirable. The cost of such a removal from Cambridge would entail an additional and unnecessary expense.

"THE TIMES" ON THE SITUATION.

We gave last week two articles from the daily Press—*The Morning Post* and *The Daily Graphic*—giving views as to the committee's report. We now add a letter which appeared in Tuesday's *Times* from an occasional correspondent:—

In your issue of October 27 you published the recommendations of the departmental committee on the Solar Physics Observatory.

secure the least thickness and disturbance of air, and a clear horizon, especially to the east, south, and west; no town smoke or glare at night; proximity to London to facilitate communication with libraries, societies, and men of science.

In choosing a site for a future observatory it was natural that the position should be so selected that in years to come the observing conditions would not be hampered or rendered less efficient by changes in the close surrounding area. When the Solar Physics Committee selected the Fosterdown site they evidently kept this condition well in mind, for an examination of it shows that it is practically impossible for any buildings or roads to be constructed in any direction which will take away from the present efficient observing conditions. Thus the site will probably be as good in 100 years' time as it is now.

Some time ago the Solar Physics Committee was informed that Cambridge had been proposed as an alternative site; the committee hesitated to accept this, pointed out

the necessity for further inquiry, and suggested an inter-departmental committee on which the Treasury, the Board of Education, the Solar Physics Observatory, and the Meteorological Office should be represented.

The committee actually appointed consisted of three persons who are or have been fellows of Trinity College, with the addition of a distinguished honorary graduate of the University of Cambridge. In the terms of reference a condition is assumed that the sum spent in the future upkeep at either place should be approximately the same as that now expended in the present observatory.

Out of the three scientific members of this committee, two, the Astronomer Royal and Dr. Schuster, agreed that the Cambridge site should be preferred, while one, Dr. Glazebrook, the director of the National Physical Laboratory, dissented.

In making a very careful examination of the report of the departmental committee, together with the evidence and appendices, it is really a matter of great difficulty to understand, in the face of the evidence offered, how Messrs. Dyson and Schuster arrived at their conclusion.

The question of site may first be dealt with. The superiority of the Fosterdown site is frankly acknowledged, and evidence is given that some of the present disadvantageous conditions at Cambridge may be much worse in the future. There is no guarantee that the land surrounding the proposed Cambridge site will not be built on, that tram-cars and other heavy traffic will not run along the main road which bounds it. In short, there is no guarantee that this part of the outskirts of Cambridge will not in the near future be an important suburb of Cambridge.

One of the greatest objections to Cambridge is touched on in cavalier fashion. Cambridge, like London, is lighted by electricity; and one of the points in favour of Fosterdown was that town glare at night would be abolished, and that long-exposure photography on the spectra of stars and nebulæ, which is carried on under bad conditions at present at South Kensington, would be rendered more fruitful of results.

As we learn from the solar physics report, this work requires at present the attendance of three assistants on every fine night.

Q. 169.—Is there any interference owing to the town light at the observatory in Cambridge?

Answer.—I do not think anything that would affect solar observations—

is all we can find on this point; and it does not suggest that we are likely to have a continuance of the study of the detailed chemistry of stellar spectra which for many years past has formed part of the routine work of the Solar Physics Observatory, and is not done elsewhere. Town glare naturally does not affect solar observations, because the sun can be observed only by day, while the town is lit only by night. But it does very seriously affect the astrophysical work of the Solar Physics Observatory, which can be carried on only at night. If it is really intended to put an end to a unique investigation of stellar chemistry and physics, the question ought surely to be debated on its merits, and not simply hustled out of sight. There is reason to fear that this is the intention, not only because of the non-recognition of anything beyond solar observation, but also because it is to be gathered from the representative who gave evidence for Cambridge that in the Cambridge view it is not simply a question of transferring the observatory, but of dismissing its staff and putting an end to it as it exists.

Of the ten members of the staff, from Sir Norman Lockyer downwards, not more than two are to be employed (Q. 222), and even none of the existing staff may be of the right "calibre" (Q. 139).

The departmental committee apparently does not accept this (Report, Section 15).

It is understood that the Government desires to relieve itself of the direct control of the Solar Physics Observatory, but that at the same time it acknowledges the value of the work done by that observatory by its willingness to continue the grant at present made for its maintenance. The inducement offered by Cambridge University to transfer control to its hands is that the University undertakes to provide a suitable building for the work, which involves no very serious expenditure. If public money to the amount of 3000*l.* a year is to be handed over to the University on account of certain specified work, then security should be taken that the public shall get value for its money, and that the specified work shall be efficiently carried on. Otherwise the transaction will merely amount to giving the University 3000*l.* a year to spend as it pleases in return for the erection of a building worth 200*l.* or 250*l.* a year.

Now in order that the work shall be carried on efficiently—that is to say, the astrophysical work, which, in spite of its title, is the speciality of the Solar Physics Observatory—it is not enough that a suitable building should be erected, even though it be manned by persons of the "right calibre." It is also necessary that the suitable building should be upon a suitable site, and the only suitable site for an observatory obviously is a site permitting its work of observation and record to be performed in the best conditions attainable. It will not be seriously argued by any responsible person that Cambridge offers the best attainable site for carrying on the astrophysical work of the Solar Physics Observatory. That work involves long exposures of sensitive plates to the light of particular stars. It is necessary that the star should be followed with the utmost accuracy in its diurnal motion, and it is obvious that vibration of the instruments due to heavy traffic in the vicinity cannot conduce to sharpness of definition. If the star has to be photographed through the illuminated haze that hangs over every well-lighted town, another serious difficulty is thrown in the way of the observer, and when spectrographic complications are added the difficulties become indefinitely more formidable.

Thus, while it may be right that the Government should rid itself of direct control of the Solar Physics Observatory, and while it may be right that Cambridge University should assume control, it cannot be right that the University should erect the observatory in Cambridge. For Cambridge is shown by the departmental committee itself to be a bad observing station for this particular work, and to be very likely to become progressively worse. A site can easily be found free from the objections that attach to Cambridge; and if astrophysical work is to be carried on at all with public money, the public have a right to demand that such a site shall be chosen. In placing the observatory at a distance from the University, Cambridge would only be following the practice of other universities, such as those of California and Chicago, which prosecute analogous researches upon the principle that observatories must be placed where the things to be observed can be best observed.

THE ENCYCLOPÆDIA OF SPORT.[1]

AS the third volume commences with hunting and concludes with racing, while it also comprises articles on lawn tennis and polo, it will be obvious that a large portion of its contents does not come within the purview of a journal like NATURE. Nevertheless, there are numerous articles connected with natural history which call for brief mention. As a whole, these articles have been brought well up to date, although in some instances there is a certain amount of repetition, and occasionally discrepancies, when two writers treat of the same subject from different points of view. The illustrations are numerous, and for the most part good (as will be evident from the one here reproduced), but the accompanying legends are in some instances not so full as is desirable. On page 85, for instance, a doe and kid are simply lettered Himalayan Ibex, while there is no indication to show whether the "Caucasian Ibex," figured on the next page, is an example of the western or eastern tur. Misprints seem to be few, although the specific name of the mule-deer is given as *nemionus* in place of *hemionus,* while its alternative

[1] "The Encyclopædia of Sport and Games" Edited by the Earl of Suffolk and Berkshire. Vol. iii., Hunting—Racing. Pp. viii + 448. Vol. iv., Rackets to Zebra. Pp viii+471. (London: W. Heinemann, 1911.) Price 10*s.* 6*d.* net; abroad 12*s.* 6*d.* net.

generic name, Cariacus, is printed with a small initial letter.

The most valuable of the natural history articles, in our opinion, is the one by Mr. Rothschild on pheasants, in which the number of species of the typical genus Phasianus is reduced from about thirty-five to half a dozen, all the forms allied to *colchicus* being regarded as local races or colour-phases of that species. As these will all interbreed and propagate fertile offspring, the new classification is far preferable to the old. In this connection it may be noted that the author of the article on partridges refers to the red-legged *Caccabis rufa* as a "variety," instead of a species. It is high time that all sportsmen who attempt to write on natural history subjects should make themselves acquainted with the respective significations of the terms species, race, and variety. Before leaving birds, reference may be made to a statement that the smooth surface of the shells of the eggs of North African ostriches is probably brought about by grinding and polishing on the part of the Arabs from whom they are generally procured. It has, however, been pointed out in *The Field* that eggs of North African ostriches laid at Woburn and Tring prove the smooth surface to be natural.

Many of the articles on big game are by Mr. H. A. Bryden, who always writes in a picturesque, if not strictly accurate, style. His worst blunder occurs under the heading Okapi, where it is stated that this animal "may be looked upon as a connecting-link between the giraffe and the antelope, having marked characteristics common to both races." If the okapi is nearly related to any family (not "race") of ruminants other than the giraffe group, it is to the deer, and not the antelopes, the alleged resemblance in bodily form to certain members of the latter group being a feature utterly devoid of systematic value.

Mr. Roosevelt communicates articles in both the third and fourth volumes on American game animals, such as peccari, prairie-chicken, pronghorn, puma, and turkey, all of which are admirable from the sportsman's point of view, although they do not enter deeply into the natural history of the subject.

From Mr R. B. Marston's excellent article on pike and pike-fishing in vol. iii. we reproduce a striking illustration of a pike feeding, other photographs in the fourth volume showing the mode in which salmon take their prey.

Among the zoological articles in vol. iv., it may be noted that the one on red deer appears in much the same form as in the original edition, the Manchurian *Cervus xanthopygus* being still affiliated to the European species instead of to the wapiti, while the Sikhim *C. affinis* is erroneously stated to come close to the latter. The rhinoceros articles, on the other hand, have been well revised, and do full justice to the discovery of the white species in the heart of equatorial Africa. In the article on the rook, Mr. Harting expresses himself as being fully convinced of the value of these birds to the farmer; and the same authority is responsible for the articles on snipe and woodcock, which appear well up to date. Sir Henry Pottinger's article on rype, or ryper (ptarmigan), illustrated (like several of the other bird-articles in this volume) by one of Mr. Thorburn's exquisite paintings, is just what might be expected from such an experienced sportsman, and the same may be said with regard to Sir Herbert Maxwell's account of the salmon. Finally, it may be mentioned that although the author of the article on trout conceals his identity under the pseudonym of "John Bickerdyke," it is satisfactory to find that his view as to the specific unity of all forms of trout is in accord with that adopted by Mr. C. T. Regan in his new book on British fishes.

Without expressing any definite opinion as to the

Photo] Pike Feeding. From "The Encyclopædia of Sport." [*J. Turner-Turner.*

purely sporting articles, we may confidently state that, in spite of a certain number of errors and shortcomings, like those mentioned above, the "Encyclopædia of Sport" supplies in the main exactly the kind of information on natural history subjects the sportsman is likely to require. R. L.

THE PROPAGATION OF EARTHQUAKE WAVES.[1]

"DOS PALABRAS," or "two little words," has a much more friendly sound than the abrupt word "preface." "Preface," standing by itself, is suggestive of a snappy military command, something like "halt" or "quick march," whilst "Dos Palabras" is the kindly invitation of a writer to the public, asking them to read his work. In the "Dos Palabras" we are told that the ordinary person only thinks about earthquake prediction and that which is utilitarian, whilst the principal object of the seismologist is to extend human knowledge about the interior of our planet.

This memoir, which was presented to the American International Congress of Science held in Buenos Ayres in 1910, although dealing especially with the propagation of earthquake waves, gives in an introduction of forty-two pages a rapid review of many problems with which modern seismology deals. From the velocity with which earthquake waves are propagated through our world, we have already learned something new about the constitution of its interior. The conclusions arrived at by these velocities as bearing upon the rigidity of our world, together with investigations made by Lord Kelvin and others on the same subject, are briefly mentioned. References are made to the investigations of Prof. Ricco which indicate a relationship between the value of gravity and the seismic and volcanic phenomena of a district. But the more general relationship between the abnormal movements of magnetic needles, earthquake disturbances, and the value of *g* in localities characterised by the presence of volcanic rocks, has been overlooked.

Sunspots, unusual movements in bodies of water, the times at which geysers erupt, barisal guns, microphonic disturbances, abnormal earth currents and other phenomena, are pointed to as subjects which should arrest the attention.

Unexpected side issues in the daily work of a seismologist—as, for example, the effect of tidal load, the transpiration of vegetation, which is always wrinkling the face of our globe, the emotional effects produced by earthquakes upon man, their effects on the behaviour of certain animals, and the exploitation of many other byways—have been overlooked. These, however, have nothing to do with Dr. Negri's chief subject, which occupies the next seventy-three pages of his publication. This entirely deals with the velocity with which earthquake motion is propagated. He starts out with the assumption that in a teleseismic record we frequently see many phases, P_1, P_2, &c., and that there are as many corresponding velocities which are distinguished as V_1, V_2, &c. He derived this idea from the publications of Dr. Ōmori. With this assumption V_1 has a velocity of about 12·5 kilometres per second, V_8 would be about 2 kilometres per second, and V_{20}, if there is such a value, would be less than 0·5 per second, *i.e.* if all these phases of earthquake motion started from an origin at the same time. We fear that many seismologists will not readily accept this hypothesis, and to explain the rising and falling in amplitude and changes in period exhibited in teleseismic writings will require some other assumption. P_1, P_2, P_3, and their corresponding velocities, are explicable by the existence of three types of waves, but the lengthening of the caudal appendage of a megaseism as it travels into and sometimes beyond its quadrantal region is a phenomenon about which many explanations have been offered, but the one to be accepted does not appear so far to have been decided on.

In his conclusion to this section, Dr. Negri says that the relation of $\frac{V_1}{V_2}$, $\frac{V_1}{V_{31}}$ (*sic*), $\frac{V_1}{V_5}$, &c., represents a series in increasing arithmetical progression. All that the majority of seismologists at present recognise is that in round numbers V_1 equals 12 kilometres, V_2 equals about 6 kilometres, and V_3 about 3 kilometres per second, and we fear that they are not yet in a position to accept values which might correspond to P_{20} or P_{40}. In an appendix the author shows that his acquaintance with modern seismology is rather one-sided. He gives a bibliography of 176 books and papers, nearly all of which are in the Italian or Spanish language. Japan is credited with thirteen papers, England with five, whilst two or three are in French. The first exhibition of seismological instruments, we are told, was represented by a section in the International Exhibition of 1900 in Paris. The exceedingly popular exhibition of earthquake instruments held in Tokio twenty years earlier is not even mentioned. The author concludes his memoir by two queries: Why do not all the students of seismology in South America combine? Why does not the national authority do something to bring about this union, which would be for the good and progress of science in general? It is my prophecy, says Dr. Negri, that these desires will very soon become realised. JOHN MILNE.

PROF. GEORGE CHRYSTAL.

THE lamented death of Prof. George Chrystal, of Edinburgh University, removes an outstanding personality in academic and educational circles. Aberdeen and Cambridge claim him as a distinguished alumnus. In 1875 he was bracketed with Prof. Burnside as Second Wrangler and First Smith's Prizeman. Even then he showed his leaning towards applied rather than pure mathematics; for Prof. Tait, who was one of the examiners, used to say that Chrystal excelled all the others in the way in which he solved physical problems.

After two years as professor of mathematics in St. Andrews University, Prof. Chrystal in November, 1879, began his life's work as occupier of the like chair in Edinburgh. The nature of his work compelled him to give his best mind to the teaching of mathematics and the training of the mathematical teacher. In those days every student of arts had to graduate in the same seven subjects. There were no options. Even the comparatively mild problem-solving mathematics of the old school, of which Kelland had been a shining light, had made many a man of classical and philosophical attainments tremble as he entered the examination hall and sat down to tackle the algebra or the Euclidean geometry paper. But the first year of Chrystal's professoriate struck terror to their hearts. Keen, rapid, logical, full of suggestions as to higher fields of mathematical delights, Chrystal transformed the whole atmosphere of the class-room. Eagerly the mathematical minds followed his fascinating lead; despondingly and despairingly those not so gifted fell hopelessly behind, faintly perceiving, if at all, the finely knit sequence

of ideas which formed the thread of his discussions. These, sad at heart, thought simply of their degree, and wondered how they were going to surmount the mathematical barrier. Chrystal had far other conceptions in his mind; but with all his strenuous and successful labours to raise the standard of mathematical teaching he was essentially just, and knew well that minds of the highest quality are not always able to appreciate the convergency of series or the mysteries of probabilities. When the time for testing came, the really intelligent, hard-working student got full credit for his limited mathematical powers.

It was a great pleasure to see in these early days the enthusiasm of the mathematical students, for whose sakes Chrystal never spared himself. The "coaches," all alive to the necessities of the situation, quickly got hold of the methods; and as the graduates passed out into the schools they carried with them the mind of their master. To Chrystal, more than to any other, the great development of mathematical teaching in the schools may be traced.

From the first, as Tait never failed to remind us, Chrystal's was essentially a physical mind. As a Cambridge undergraduate he had—as some thought—"wasted" his time with Maxwell in the Cavendish Laboratory, fiddling with wires, when he should have been practising the writing out of problems. His careful investigation into the truth of Ohm's law is a standard piece of work showing clear perceptions and careful manipulation. The articles on "Electricity" and "Magnetism" in the ninth edition of the "Encyclopædia Britannica" contain in a wonderfully small compass the very best up-to-date account of these sciences, both theoretical and experimental, ever put together. Had they been printed in book form a few years after their first publication they would have been the *vade mecum* of the advanced student. Their merits are a clear, flowing, forceful style, and a remarkable discrimination in selecting material. The great advances of the last twenty years have been along the lines clearly indicated in these articles. On coming to Edinburgh, Chrystal, though he gave his principal attention to his real class work, did not allow his physical work to fall behind. There was no summer session in those days; and the summer months which most other professors spent in holiday were spent by Chrystal in Tait's laboratory. Here he brought to full fruition his theory of the differential telephone. His paper on the subject is published in the Transactions of the Royal Society of Edinburgh, and constitutes the first truly scientific discussion of the action of the induction-balance.

Outside his own particular experimental work, Chrystal was an ever-present source of inspiration to the students. Several of the investigations which were carried through in Tait's laboratory during the early 'eighties were suggested by Chrystal, who really acted the part of a second professor of natural philosophy. With the increasing care of his own department, he was compelled after a few years to give up his experimenting. Another reason, as he once expressed it, was that he found he was usurping the use of all the best instruments in the place, so that the students were not able to get their best work done.

The personality of Prof. Chrystal soon made itself felt on board and senate. He was elected a vice-president of the Royal Society of Edinburgh in 1887, at the unusually early age of thirty-six. For two terms of six years he filled the same important post, and, in 1901, on Prof. Tait's death, he was chosen general secretary. The duties of this office he performed in a manner which it is impossible to praise too highly. Only a man of Chrystal's alertness of mind, clearness of vision, knowledge of affairs, fair-mindedness, and yet determination to have the society's rights recognised, could have successfully manœuvred the society through the time of strain when its status and efficiency were threatened. The Scottish members of Parliament stood loyally by the society, and by their sympathy more was achieved than was at first hoped for. Through all the cross-currents of opinion, it was Chrystal who was the real steersman. The present habitation of the Royal Society of Edinburgh is a lasting monument to the memory of its general secretary, who secured from the Government of the day a generous recognition of the claims of science.

The same keen personality combined with business faculties of a high order made Chrystal the right man in the right place, when in 1891 his colleagues elected him the dean of the faculty of arts. The new ordinances which came into effect at that time were soon found to be hampering and unworkable in the interests both of teacher and pupil. Strenuously Chrystal applied himself to the reorganisation of the whole arts curriculum, and the reward of his labours he lived to see in the sanctioning of a new ordinance which grants autonomy to each university within reasonable limits.

To these administrative duties he added for some years the chairmanship of the Provincial Committee for the Training of Teachers. He was, in fact, the first chairman, and probably did more than any other single man to mould this committee into a serviceable administrative body. He was also for several years a member of the committee appointed by the War Office to advise the Army Council regarding the preliminary education of officers.

With all this administrative strain, Chrystal continued to develop his department of mathematics to greater and greater effectiveness. His text-books on algebra are well known; but it is not perhaps so well known that he was the inventor of the very appropriate phrases the "freedom equations" and the "constraint equation" of a curve. These show again how his mind moved in dynamical regions.

Chrystal's literary output is perhaps smaller in quantity than that of most men of equal reputation; but the quality is high. He communicated to the Edinburgh Mathematical Society an admirable account of the properties of lenses and doublets, to the study of which he was led in his recreation as a photographer. He was very skilful in all photographic manipulation, his attachment to the art dating from his Cambridge days, when dry plates were unknown.

In addition to several mathematical papers in the Proceedings and Transactions of the Royal Society of Edinburgh, he enriched the science of hydrodynamics by his researches on seiches. His attention was directed to the subject by Sir John Murray, and the whole problem, experimental and theoretical, seized hold of his mind in a marvellous way. This recent work is too well known to need discussion now. Not only did he vastly improve the mathematical theory of these movements in lakes and bays, but he invented instruments and obtained records which shed a new light on the whole set of phenomena. The work is stamped with all the thoroughness and ingenuity of a fine intellect.

What Chrystal undertook to do he did to the utmost of his powers. He left no ragged ends. All was carried through with celerity, yet with thoughtfulness and accuracy. Quick in his apprehension, and impatient of humbug, he was a terror to the student who was not an honest seeker after truth, but to the genuine student he gave of his best, and nothing delighted him more than when a pupil showed originality and power of research. His knowledge of human affairs was wide and deep. He was splendid

company among congenial friends, and in his own home he was the best of hosts. He was remarkably regular in his attendance at the meetings of the Royal Society Club, and there his appreciation of a good story and his own powers as a raconteur were always in evidence. Like most Scotsmen, he was reserved in his expression of the deeper feelings, but his sympathies were true and his friendship staunch.

C. G. KNOTT.

NOTES.

HIS MAJESTY THE KING has been pleased to approve of the following awards this year by the president and council of the Royal Society:—a Royal medal to Prof. George Chrystal, Sec.R.S. Edinburgh, for his researches in mathematics and physics, especially his recent work on seiches and free oscillations in the Scottish lakes; and a Royal medal to Dr. W. M. Bayliss, F.R.S., for his researches in physiology. The following awards have also been made:—the Copley medal to Sir George H. Darwin, K.C.B., F.R.S., for his scientific researches, especially in the domain of astronomical evolution; the Davy medal to Prof. Henry E. Armstrong, F.R.S., for his contributions to chemical science; and the Hughes medal to Mr. C. T. R. Wilson, F.R.S., for his investigations on the formation of cloud and their application to the study of electrical ions.

THE following is a list of those who have been recommended by the president and council of the Royal Society for election into the council for the year 1912 at the anniversary meeting on November 30:—*President*, Sir Archibald Geikie, K.C.B.; *treasurer*, Mr. Alfred Bray Kempe; *secretaries*, Sir Joseph Larmor and Sir John Rose Bradford, K.C.M.G.; *foreign secretary*, Sir William Crookes, O.M.; *other members of the council*, Lieut.-Colonel A. W. Alcock, C.I.E., Prof. W. H. Bragg, Sir A. H. Church, K.C.V.O., Mr. L. Fletcher, Prof. J. S. Gardiner, Mr. W. B. Hardy, Prof. M. J. M. Hill, Prof. F. S. Kipping, Mr. H. R. A. Mallock, the Duke of Northumberland, K.G., Sir Ronald Ross, K.C.B., Prof. E. Rutherford, Prof. S. P. Thompson, Prof. Sir J. J. Thomson, Mr. H. W. T. Wager, and Prof. E. T. Whittaker.

A REUTER message from Stockholm states that the Swedish Academy of Science has decided to award the Nobel prize for chemistry to Mme. Curie. Prof. W. Wien, professor of physics in the University of Würzburg, is to receive the prize for physics. The value of each prize this year is 7773*l*.

WE regret to see the announcement of the death of Mr. John Brown, F.R.S., of Longhurst, Dunmurry, Belfast, on November 1, at sixty-one years of age.

THE Physical Society's annual exhibition will be held on Tuesday, December 19, and will be open both in the afternoon and evening.

THE Berthelot memorial lecture of the Chemical Society will be delivered by Prof. H. B. Dixon, F.R.S., on Thursday, November 23.

THE eighty-sixth Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Dr. P. Chalmers Mitchell, F.R.S., secretary of the Zoological Society, his subject being "The Childhood of Animals."

THE death is announced of M. E. F. André, whose works in landscape gardening are widely known in the horticultural world. Among various books of which he was the author are "L'Art des Jardins," 1879, with numerous plates and more than 500 illustrations in the text, and a volume on the bromeliaceous plants collected in Colombia, Ecuador, and Venezuela. For nearly thirty years he edited *La Revue Horticole*, which has always held a high place among botanical periodicals.

THE Royal Geological Society of Cornwall at its annual meeting on October 31 presented the Bolitho gold medal to Mr. Clement Reid, F.R.S., in recognition of the able and conscientious manner in which he had superintended, during the past ten years, the geological resurvey of the county, the final memoirs of which are in the press. Mr. Reid, in returning thanks, said that the work done has widened the horizon and opened up new possibilities for Cornish geologists; but there is still a great deal to be done.

THE Royal Society of Arts will begin its 158th session on Wednesday, November 15, with an address from Lord Sanderson, G.C.B., the chairman of the council. Five meetings are announced before Christmas, at which papers will be read on the industrial progress of America, by Prof. James Douglas; the efficiency of the aëroplane, by Mr. A. E. Berriman; British Guiana, by Mr. J. A. J. de Villiers; London transport, by Mr. W. Yorath Lewis; and Bengal fisheries, by Dr. J. Travers Jenkins. Four Cantor lectures on "The Carbonisation of Coal" will be delivered by Prof. Vivian Lewes, and two juvenile lectures on "Soap Bubbles" will be given in January by Mr. C. V. Boys, F.R.S. A long list of papers for the meetings to be held after Christmas is also published.

THE winter session of the British Fire Prevention Committee was commenced on November 1 with a meeting to conduct a series of fire tests dealing with a small hand extinguisher intended to put out electrical and petrol fires. There was a large attendance at the committee's Regent's Park Testing Station, the Earl of Londesborough, K.C.V.O., Mr. Alexander Siemens, and Mr. Edwin O. Sachs, members of council, receiving the visitors, among whom were leading officials concerned in fire matters from the War Office, Board of Trade, and other public departments. There will be another series of tests this month dealing with the flannelette question, which is of such importance to child life; and in December some fire-resisting doors and partitions from the United States will be under investigation.

AUTHENTIC details of the recent Wright gliding experiments are now to hand, from which it appears that the machine used was very similar to a recent type of Wright aëroplane with power. The glider had no front elevator, but an elevating tail placed 12 feet in the rear of the trailing edge of the main planes. The dimensions of the main planes were 32 feet by 5 feet respectively, with a smaller camber than that used in the powered machine. Otherwise the only alterations made were to increase the size of the vertical rudder in the rear and to cut down the length of the skids. With this glider Mr. Orville Wright, starting from one of the sand-hills near Kill Devil Hill, twice succeeded in remaining in the air for rather more than 1m. 25s. The height of the hill from which he started was 75 feet. With regard to the automatic stability device which is stated to have been tried, no details are yet available. The objects of the gliding trials were to decrease the head-resistance of the machine, and incidentally to solve in a practical manner several problems in wind pressure.

BY the death, at the age of seventy-one, of Mr. W. Irvine, a retired member of the Indian Civil Service,

Oriental studies in this country have suffered a grievous loss. Mr. Irvine during a long and distinguished service in India acquired a singularly wide knowledge of the vernacular languages and of Persian. He was one of the few scholars who devoted himself to the history of the later Mogul period. His published work largely consisted of papers contributed to the Journal of the Royal Asiatic Society and other periodicals devoted to Oriental learning. These displayed his wide acquirements in history and philology, and his generous sympathy with India and her people. His more important works were an elaborate account of the armies of the Moguls, and an admirable edition of the famous "Storia do Mogor," or Mogul India between 1653 and 1708, the record of his journeys and experiences by the Venetian traveller, Niccolao Manucci, which was published in four volumes in the Indian Text Series.

THE protest recently made by Lord Curzon against the action of the Indian Government in proposing the suppression of the Central Department of Archæology was strongly supported in these columns and by the numerous scientific bodies and individuals in this country who are interested in the preservation of historical monuments and the excavation of ancient sites. In addition, it has been shown conclusively that the work of the department had commended itself to the native princes and to all classes of the population who look back with pride upon the splendid buildings—the work of vanished races and dynasties. In the course of the debate on the subject, raised by a motion from Lord Curzon on November 3, the Secretary of State, the Marquess of Crewe, announced that while the Government agreed with the contention of the Government of India that the proposed reorganisation would not necessarily put an end to the work of conservation and excavation, he, as representing the Council of India, took the view "that it is necessary to retain the central department for advice, for general supervision, and for the collection of information in connection with archæology." This satisfactory result of the controversy, for which all students of art and history are indebted to Lord Curzon, will be received with general approbation.

THE "Uto" photographic paper of Dr. J. H. Smith, which when exposed under a coloured transparency would furnish a coloured copy of the transparency, was referred to in these columns two or three years ago when it was placed on the market. For some time past it has been unobtainable; and it was known that Dr. Smith was seeking to perfect it. The Société Anonyme Utocolor of La Garenne-Colombes, Paris, is now introducing an improved paper under the name of "Utocolor-paper," which embodies the results of Dr. Smith's investigations. The new paper is stated to be much more rapid than the old, and it is free from the odour of anethol, the sensitiser previously employed. The gelatinous coating of the paper contains three dyes, red, yellow, and blue, which are bleached by exposure to light; and if a coloured light is employed, the dye, or mixture of dyes, that matches the colour of the light survives longer than the other dyes, which absorb the light, and therefore a coloured original is reproduced. The exposure necessary to copy an autochrome is about two hours of direct sunshine, or several hours of good diffused light and one hour of sunshine to finish it. Coloured light-filters are supplied, and one or both of them are placed over the frame during the exposure. They serve to absorb the ultra-violet and adjust the comparative colour intensities. The paper after exposure is desensitised, or "fixed," and the prints may then be kept in a feebly lighted room for a considerable time without obvious change; and in the dark, as in an album, they may be regarded as practically permanent.

THE recently founded Prehistoric Society of East Anglia has issued the first instalment of its Proceedings for 1908–9 and 1909–10. It is mainly devoted to inquiries and speculations regarding certain types of flint implements found by the president, Dr. W. Allen Sturge, and his fellow-members. He remarks that "not only is our district of East Anglia one of the richest in the world for the older Palæolithic remains, but it is probably the richest—I might perhaps go further and say incomparably the richest—in the world in Neolithic remains." The work of such a society will be welcomed by all students of prehistoric man and his culture. Dr. Sturge's essay discusses in detail the peculiarities in the types of implements which he has discovered. These lead him to attribute to them a higher antiquity than is recognised by other authorities. At any rate this essay, which is well provided with illustrations, deserves serious attention.

DR. REDCLIFFE N. SALAMAN contributes to *The Eugenics Review* for October an interesting paper entitled "Heredity and the Jew." Of the ancient race he observes that it is unlikely that any people residing in the centre of the great highway of the Old World, as did the Jews and their neighbours, should have, at any time, maintained a biological purity as we understand it in the animal and plant world. Proceeding to discuss certain cases of mixed marriages between Jews and Gentiles, he arrives at the conclusion that "the Jewish facial type, whether it be considered to rest on a gross anatomical basis or whether it be regarded as the reflection in the facial musculature of a peculiar psychical state, is a character which is subject to the Mendelian law of heredity." The obvious criticism is that the materials are too scanty to warrant this conclusion. The paper, however, suggests an interesting field of inquiry, which the writer might with advantage study on a wider scale.

AT a recent demonstration given by Prof. A. Keith at the Royal College of Surgeons, Lincoln's Inn Fields, a series of preparations were shown which illustrate the remarkable growth changes which occur in the bodies of those suffering from acromegaly. Not only was the skeleton affected by a peculiar form of overgrowth, but so were the muscles, the viscera, the joints, the heart, and the lungs. Even the coats of the appendix were increased. Many of the features of the skeleton recalled those of Neanderthal man. The great enlargement of the ribs, sternum, and clavicles produced a thorax which had many points in common with that of the gorilla. The pituitary body was greatly enlarged. It becomes more evident, as our knowledge of acromegaly is extended, that the pituitary body has a profound influence on the growth of the body. It is generally recognised that it coordinates in some manner the growth of the skeleton and muscles, but it is becoming manifest that it also influences the other systems of the body. A great development of these bones and muscles would be useless to the individual unless there was a corresponding hypertrophy of the heart, lungs, and of the viscera connected with nutrition. The preparations added recently to the College of Surgeons Museum show that all these systems are affected. One of the preparations illustrates a very remarkable structural change. In the subject of the disease, a male, the pelvis had assumed by a process of growth all the characters of the female pelvis

DR. F. NANSEN, G.C.V.O., lectured before the Royal Geographical Society on the Norsemen in America on November 6. The preparation of a short account of Arctic exploration had led him to review the whole of the evidence for the early voyages of the Norsemen, and resulted in views which differ considerably from those that are current. He agrees that the attainment of the shore of America by the Norsemen is certain, but maintains that the accounts of their voyages as we find them in the Icelandic sagas is at least in part legendary. Though Greenland, Helluland, Markland, and Wineland were discovered at the end of the tenth and the beginning of the eleventh centuries, the earliest written saga treating with these voyages was written between 1270 and 1300. He attributes the details of the self-grown vine and the unsown corn (or wheat) to interpolations and additions taken from earlier writings, such as those of Isidor Hispalensis from the seventh century, when writing of the Fortunate Islands in the Atlantic west of Africa. The same ideas in very similar words are seen to occur in the early Irish writings. His conclusion is that the whole narrative of the Wineland voyages is a mosaic of one feature after another gathered from east and west, among which we find many features, however, which indicate a certain knowledge of the real conditions on the north-east coast of America.

AT the conclusion of an article on the habits of the Amazonian ant *Polyergus rufescens*, published in vol. xxxi., p. 695 (October), of *Biologisches Centralblatt*, Prof. C. Emery states that the foundation of a new colony of this species is doubtless due to one or more fertilised females effecting an entrance into a nest of *Formica fusca* or one of its subspecies. The intruding female, unless she be stopped by hostile workers, immediately makes her way to the domicile of the reigning queen, whom, when found, she attacks and eventually kills with her powerful mandibles. During the contest the attendant workers remain stupefied with fright, but at the death of their legitimate queen quickly receive the foreign female in her place. In the second year the new queen lays eggs, from which emerge polyergus-workers, and these eventually obtain the mastery of the nest.

THAT certain fishes, such as salmon, which ascend rivers or streams for spawning assume two, or rarely three, distinct phases has long been known; and in a recent issue (vol. vii., part v.) of *Annotationes Zoologicae Japonenses* Prof. S. Hatta shows that the same thing occurs in the lesser Japanese river-lampern (*Lampetra mitsurikii*). Males and females of this species are readily distinguished by the much greater development of the anal fin in the latter than in the former; and as representatives of each sex are found in both a large phase, which attains a length of about 8 inches, and in a small phase, in which the length is less than half this, it is manifest that the species is dimorphic, especially as the two phases are found in one and the same stream, and do not intergrade.

A SERIES of nine associated human teeth discovered in a stratum of Mousterian age in a cave at St. Brelade's Bay, Jersey, are referred by Messrs. Keith and Knowles, in the October number of *The Journal of Anatomy and Physiology*, to the Neanderthal race. In spite of the slight degree in which the cusps are worn, the pulp-cavities of several of the teeth were found to be filled with secondary dentine. This and the size of the roots the authors regard as characteristic of Neanderthal teeth. Other primitive features are noticeable in the canine and first lower premolar, which (in contrast to what obtains among modern races) is larger than the second, in consequence of having to serve as an opponent to the upper canine.

WITH the view of illustrating normal variations in form and size of chromosomes, Dr. C. E. Walker figures, in a note received as a separate abstract from *Archiv für Zellforschung* (vol. vi., part iv.), certain changes observed during the meiotic division in cells of the generative organ of Triton and Lepidosiren. Arising therefrom, the argument is formulated that if the chromosomes are the bearers of individual variations, the differences in form and size may be correlated with the fluctuating variations recognised by Darwin.

A REPORT on official investigations regarding "beech coccus," *Cryptococcus fagi*, conducted by Mr. L. A. Boodle and Mr. W. Dallimore, is published in the *Kew Bulletin* (No. 8). Personal observations were made in woods in Buckinghamshire and Berkshire. The evidence is not thoroughly conclusive, but the investigators express a definite opinion that the beech coccus is not the destructive agent as generally supposed, and implicate the two fungi *Nectria ditissima* and *Melogramma spiniferum*, both of which were universally found on the unhealthy trees. Another article in the *Bulletin*, of considerable interest to gardeners, is the note on peat-moss litter manure, in which it is stated that the material is neither true peat nor moss, and is extremely undesirable in gardens, being injurious unless it has been allowed to rot for two years at least; the injurious action is attributed to the excess of organic acids contained.

As a practicable study in the evolution of a land-form and its plant covering, Dr. L. Cockayne describes, in a contribution—of which a separate copy has been received—to the Transactions and Proceedings of the Botanical Society of Edinburgh (vol. xxiv., part iii.), the series of events which have led to the colonisation of the subalpine river-bed of the Rakaia, in the southern Alps of New Zealand. The climatic conditions point to an excess of rain, neutralised by insolation, frost, and high winds, while controlling edaphic factors are supplied by the porous soil and glacial water, so that the early colonists must be able to endure severe ecological changes. The first stages in colonisation are supplied by *Epilobium melanocaulon*, a plant provided with light, rapidly germinating seed, and the mat-forming *Raoulia tenuicaulis*. On situations raised above floods these are reinforced by a crustaceous lichen and other species of Raoulia, notably *R. Haastii*, which serves as a nidus for various less hardy colonists. A steppe association, distinguished by the presence of Raoulia and tussock grasses, and scrub are subsequent stages.

IN all new countries it is necessary to discover new crops in order that the system of agriculture should be diversified as much as possible, and particularly is it desirable to introduce leguminous crops. In a recent issue of *The Agricultural Journal of the Union of South Africa* experiments are reported showing that the soya bean is likely to prove advantageous wherever maize is of great importance. The crop is not only valuable in itself, but it leaves nitrogenous residues in the soil that add materially to the fertility. The seeds are rich in oil, for which there is a considerable demand by soap-makers and others, while the residue left after partial extraction of the oil furnishes useful cattle food.

As a reply to the statement, formulated in a memorandum issued by the U.S. Weather Bureau, questioning

whether it can be shown that deforestation has augmented droughts and floods, an article is published in *The Indian Forester* (September) citing data and observations to prove that forests do exercise a marked influence on the regulation and maintenance of water supplies. The evidence submitted falls under three heads. First, deforestation produces a diminution or cessation of flow in the streams; most of the examples quoted belong to this category. Testimony from Monroe, Wisconsin, affirms that in seventy years the forest region has been reduced from 83 to 6 per cent.; coincidently, streams have dried up entirely, and mills have ceased to operate. Secondly, reafforestation leads to an increased water supply. An instance from Burma is noted, according to which renewal of the forests on Popa Hill, Myingyan, has averted the periodic drying up of the streams. Thirdly, corroborative conclusions are derived from a comparison of the flow in neighbouring streams, fed in one case from protected, in the other from denuded, catchment areas.

THE Board of Agriculture issues leaflets calculated to serve a very useful purpose by giving information to farmers on such problems as plant diseases, crop management, and manures. The leaflets are short, concisely worded, and where possible illustrated. Some of the recent issues deal with bacteriosis of the potato and tomato; actinomycosis in cattle, a disease caused by the growth on the animal's tongue of the parasitic fungus Actinomyces coming from grasses, cereals, or the soil. Another leaflet deals with the three weed grasses *Triticium repens*, *Agrostis vulgaris*, and *Arrhenatherum avenaceum*, all described by the farmer as couch or twitch; whilst a third gives an account of the composition of seaweed and its use as manure.

THE eleventh annual report of the Midland Agricultural and Dairy College shows that the members of the staff are responding in a splendid manner to the demands made on them by students and farmers. The principal says of one of the departments: "Every use has been made of the time and facilities that are available, and often leisure that ought to have been spent in recreation has been devoted to extra work," a statement fully borne out by the separate reports from the individual members of the staff. The Board of Agriculture has increased the grant to the maximum of 1000*l*., but more space seems to be needed in several departments. Favourable reports were sent by the examiners, except only in one instance, and there a perusal of the examination questions shows that the fault lies with neither students nor staff.

THE summary of the weather for the week ending November 4, issued by the Meteorological Office, shows that the conditions were very stormy throughout the period. Several large and important storm areas arrived from the Atlantic and extended over the British Islands and their neighbourhood. Severe gales were experienced on several days during the week, and on Saturday, November 4, the barometer at Thorshavn fell below 28·0 inches as the central area of the storm traversed Færöe. The rainfall for the week exceeded the average in all districts except in the north-east of England and in the English Channel. In the west of Scotland the measurement was 3·89 inches, which is 2·59 inches more than the average, and in the north of Scotland the excess was 2·29 inches. The aggregate rainfall for the nine weeks of the present autumn is now in excess of the average in the south-east and north-west of England, in the English Channel, and in the south of Ireland, whilst the deficiency in other districts is being greatly lessened by the recent heavy rains. At Greenwich the rainfall for October was 3·29 inches, which is 0·44 inch more than the average of the past sixty years; and October was the wettest month since November of last year.

AMONG several useful papers in the Journal of the Meteorological Society of Japan for August is one, by Mr. Y. Tsuiji, on earth temperature at Taihoku (Formosa), based on eleven years' observations (1897–1907). The surface layer of the ground is clay, and underground water is met with at a depth of about 20 feet. The tables show that the average annual air temperature is 21·54° C., and at the surface of the ground 23·55°; at 0·5 metre the mean is 23·39°, at 1 metre 23·31°, at 3 metres 23·11°. The mean decreases with depth, while the rate of diminution also becomes smaller as the depth increases; the annual range diminishes with increase of depth, while the epoch of extreme temperature is retarded. The author submits the results to harmonic analysis, and remarks that they show that if we are satisfied with a rough determination of the mean values for practical use, there is no need for that laborious process adopted in modern meteorology.

IN *The Cairo Scientific Journal* for September details are given of a slight earthquake shock which was felt in Cairo on August 22 at 10h. 23m. east European time. It was characterised by the very rapid character of the vibrations.

IN *Petermann's Mitteilungen* for October the results of the census of Mexico taken in October, 1910, are discussed and presented in a map which shows the distribution of population density. The northern portion to the north of lat. 25° is scantily peopled, having a population of from one to three to the square kilometre. The most densely peopled region is in the central part by Mexico, where a small portion is shown as having 480 inhabitants per square kilometre.

WE have received a catalogue of surveying and drawing instruments made by Messrs. C. F. Casella and Co., Ltd., of 11 Rochester Row, London, S.W. Besides the usual types of instruments, this firm constructs several of a special character, and full descriptions of some of these are given in the catalogue. Among these we may note Reeves's tangent micrometer for use on sextants and theodolites; Reeves's distance-finder alidade, in which the 3-foot alidade rod can be utilised as a distance finder, so that when used on a plane table the distance of objects can be determined either by intersection or by direct measurement. Hepworth's electric artificial horizon is a simple attachment by which, when a line on the horizon glass is in alignment with the eye of the observer and the natural horizon, the observer is notified by an audible signal, so that the use of the sea-horizon is no longer necessary, and observations can be taken when fog or mist may obscure the horizon.

THE Journal of the Franklin Institute for October contains an abstract of a paper on the *rôle* of water in minerals, by Dr. W. W. Coblentz, of the Bureau of Standards, Washington, which gives an account of a method of investigating the question which seems likely to furnish more definite information than has been available in the past. Dr. Coblentz examines the infra-red absorption spectra of a number of minerals having water of crystallisation by means of a vacuum bolometer and a mirror spectrometer. He finds that in some cases the absorption spectrum of the crystal is not, while in other cases it is,

the superposed spectra of the anhydrous substance and water. The water in crystals of the first class he proposes to call "water of constitution," and in the second "water of crystallisation." The latter term would thus include water which has in the past been known as "water of crystallisation," "dissolved water," and "water of solid solution."

THE diurnal variation of magnetic declination at Kiel is discussed by L. Weber and H. Borchardt in a paper in Heft 1, Bd. xv., of the *Naturwissenschaftlichen Verein* for Schleswig-Holstein. The data, derived from a magnetograph of special construction, extended—with two or three short interruptions—from January, 1902, to September, 1910. The range of the regular diurnal variation in individual months varied from 2·8′ in December, 1905, to 12·8′ in July, 1906; while the range of the mean diurnal inequality for the year varied from 6·63′ in 1909 to 8·46′ in 1905. At the end are curves showing the diurnal variation for the twelve months of the three years 1907 to 1909 treated individually, and for the twelve months of the seven years 1903 to 1909 combined, as well as the mean diurnal variation for the year from the last-mentioned period.

THE recent study of white plumage and hair coloration has led to the interesting conclusion that there are two varieties of white, one of which is dominant and the other recessive. These are indistinguishable to the eye, but exact opposites from the breeder's point of view. Dr. R. A. Gortner, working in the biochemical laboratory of the Carnegie Institution, has shown recently (*Journal of Biological Chemistry*, September) that dominant whites do not contain a melanin which is lacking in the recessive whites; he attributes dominant whites to the presence of a factor which inhibits pigment formation. His experiments prove that the oxidation of tyrosine by tyrosinase is prevented by the presence of aromatic phenols, which contain two hydroxyl groups in the meta position to each other, such as resorcinol, orcinol, or phloroglucinol. These phenols do not inhibit other oxydases than tyrosine. It is supposed that in dominant whites such an inhibiting factor is present, whereas the recessive whites lack enzyme or chromogen or both, and also lack the inhibiting factor.

Engineering for November 3 comments on the report of the commission appointed to inquire into the cause of the *Liberté* explosion, which has now been made public. Briefly, the report states:—(1) That it was not due to an act of malevolence. (2) That it was not due to a fire having occurred in any of the spaces adjoining the magazines. (3) That it was due to the inflammation of a cartridge of service powder in one or other of the forward starboard magazines containing only powder from one lot—namely, lot BM_{13} AM_8 2·06 P.B.—*i.e.* the second lot of powder manufactured in 1906 at the Government powder factory of Pont-de-Buis. The commission hesitates to attribute the cause to "spontaneous combustion" of the powder. Among other recommendations, the report states that the recent order lowering to four years the limit of age allowed for powders stored on board will be, without doubt, for a long time yet one of the most efficacious guarantees of safety against the instability of "B" powders; in foreign navies the limit of age is even lower.

OUR contemporary points out that British cordite is tested as soon as possible after it becomes eight years old, and though inspection is made twice yearly of all cordite, it is clear that it is expected to last at least eight years. Germany and Italy both use nitro-glycerine powders for their navies, which, so far as is known, have been immune from trouble as regards powder. Possibly the United States regulations are referred to, since the U.S. Navy use a nitro-cellulose powder—*i.e.* the same type as the French Navy. *Engineering* holds that the report confirms its already published views that, for naval purposes, the nitro-cellulose type of propellent powder is vastly inferior, both chemically and ballistically, as compared with the nitro-glycerine type. Indications are not wanting that the U.S. Navy may have to deplore a similar disaster, as it has lately adopted the course of "reworking" its "old" powders, some of them only a couple or so years old, with so-called stabilisers. These may have their uses when added to newly made powders; but to add them to powders which have already shown themselves to be unstable, from the fact that they are sentenced to be reworked, is a dangerous expedient which no economic consideration can excuse.

MR. W. MARTINDALE, New Cavendish Street, London, W., has issued a new complete price-list of apparatus, chemicals, and appliances generally suitable for scientific chemists and medical practitioners. The catalogue runs to 182 large pages, is well illustrated, and arranged in a form handy for reference.

MANY valuable works—old and new—are included in a catalogue of second-hand books on meteorology and terrestrial magnetism just issued by Messrs. H. Sotheran and Co., 43 Piccadilly, W. Brief notes are given describing the characters of most of the books. The catalogue includes also a collection of works on airmanship, and a supplement of cognate periodicals and publications of learned societies.

AN illustrated supplement, 1911, to the catalogue of scientific apparatus issued in 1910 by Messrs. Heynes Mathew, Ltd., of Cape Town, serves to show, incidentally, the satisfactory way in which the teaching of science is being developed in South Africa. The science teachers in South African schools are now able to obtain locally the equipment and material necessary for their work. The present list shows that this firm is in a position to undertake the complete furnishing and equipment of laboratories.

THE *Revista Tecnica del Ministerio de Obras Publicas* of Venezuela for September contains a note on the calculation of geographical coordinates and azimuths for a geodetic triangulation on which a physical and political map of the country may be based. The values for Clarke's ellipsoid of 1866 are used, and the Coast and Geodetic Survey of the United States is followed for the logarithms of the different constants involved in the computations.

AMONG notices of forthcoming scientific books which we have received during the week may be mentioned the following:—Messrs. Methuen have in the press a book by Mr. R. Lydekker, F.R.S., entitled "The Ox and its Kindred." Commencing with a discussion as to the proper English name of the domesticated animal, the author gives a sketch of the structure and zoological position of oxen, followed by a history of the extermination of the wild ox, or aurochs. Accounts are also given of park-cattle and the chief domesticated breeds of cattle—British and foreign; the book concludes with brief surveys of the wild and extinct members of the group.—Messrs. Kegan Paul, Trench, Trübner and Co., Ltd., are publishing under the title of "North Sea Fishers and Fighters" a work, by Mr. Walter Wood, on the development of the deep-sea

fisheries. The book deals fully with the men of the North Sea, and is embellished with colour and pencil drawings and photographs.—Mr. William Lewis, of Duke Street, Cardiff, is publishing for the Cardiff Naturalists' Society the first volume of "The Flora of Glamorgan," including the spermaphytes and vascular cryptogams, with index. The work has been prepared under the direction of a committee of the Cardiff Naturalists' Society, and is edited by Prof. A. H. Trow.

OUR ASTRONOMICAL COLUMN.

BROOKS'S COMET, 1911*c*.—In addition to the ordinary cometary spectrum, M. Bosler finds radiations at λλ 407, 405, 401, and 399 in the spectrum of the head of Brooks's comet. A longer exposure on September 25 showed also the tail radiations, and it was seen that λλ 401, 425, and 456 extended some 1° 30′ into the tail, while the radiation at λ 470 extended for not more than 30′.

Prof. Iniguez, describing the photographs secured at the Madrid Observatory (*Comptes rendus*, No. 17, October 23), records seven condensations in the spectrum, viz. λλ 555, 514, 472, 440, 423, 410, and 388. But the fourth and sixth are multiple, the wave-lengths of their components being 440, 434 and 432 and 410, 407, 405, 404, and 402 respectively; λ 388 is double.

The comet is still visible near the horizon, south of east, just before daybreak; but, as will be seen from the following ephemeris, by Dr. Ebell, the southern declination is increasing, and the comet, receding from both sun and earth, is becoming fainter:—

Ephemeris 12h. M.T. Berlin.

1911	α (true) h. m.	δ (true) ° ′	log *r*	log Δ	mag.
Nov. 8	12 43·9	− 9 48·9	9·7531	0·0263	3·9
,, 12	12 51·6	−14 10·4	9·7918	0·0558	4·2
,, 16	13 0·3	−18 3·6	9·8317	0·0824	4·5
,, 20	13 9·4	−21 31·7	9·8709	0·1063	4·9

BORRELLY'S COMET, 1911*e*, AND WOLF'S COMET, 1911*a*.—A telegram from Dr. Meyermann to the *Astronomische Nachrichten* announces that Borrelly's comet was observed at Tsingtau on October 20. It was elongated, about 2′ in diameter, magnitude 10, had no tail, and was very indistinct.

M. Kamensky gives an ephemeris, extending to January 2, 1912, for Wolf's comet in No. 4528 of the *Astronomische Nachrichten*. Only four observations of this faint object during the present return have yet been recorded; these give corrections of the order of −0·5s. and −6″ to the ephemeris. Taking the magnitude on June 29·5 as 14·6, as determined from Dr. Wolf's plate, M. Kamensky finds that at no time this year will the comet be brighter than the fourteenth magnitude.

MARS.—M. Antoniadi's observations of Mars with the large refractor at the Meudon Observatory commenced on September 18, and a number of changes have already been noted. Modifications of the colours of various parts of the disc, with an abnormal pallor of the "seas," suggests the presence of yellowish cloud in the Martian atmosphere, such as has been noted at previous oppositions. A large mass of white cloud completely veiled the region of M. Cimmerium, M. Tyrrhenum, and Hesperia on October 14. The complete veiling of so dark an area as M. Tyrrhenum has not been seen since 1888, when the series of observations commenced. The whiteness of Libya on October 11 is attributed to overlying mist, which is transparent when viewed normally, but increases in visibility as the line of vision becomes more oblique, *i.e.* as the area approaches the terminator. A very bright terminator projection, probably due to cloud, was a very prominent feature of the regions north of Icaria from 10h. 56m. to 11h. 25m. on October 14; terrestrial clouds then stopped observations (*Astronomische Nachrichten*, No. 4532).

THE SUN'S ENERGY SPECTRUM AND TEMPERATURE.—In No. 3, vol. xxxiv., of *The Astrophysical Journal* Mr. Abbott discusses the distribution of energy in the sun's spectrum as derived from the spectro-bolometric observations made at Mount Wilson, Mount Whitney, and Washington during 1903–10. He discusses at length the various possible errors and the conditions which might modify, more or less, the derived results. The distribution of energy outside the atmosphere is tabulated, and the energy is shown to reach a sharp maximum at about 0·470 μ; a table of atmospheric transmission coefficients is also given. The results appear to be independent of the observing station, but sensitive to the character of the spectroscope used, and little weight must be given to values for wave-lengths beyond 0·40 μ where glass prisms are employed; a quartz-magnalium system was used latterly.

Mr. Abbott also discusses the question of the sun's temperature, and finds that the sun's effective emission is comparable with that of a "black body" at 6000° C. absolute, although he considers this is modified considerably, and that the actual radiating temperature is more of the order of 7000° C. absolute.

A DAYLIGHT METEOR IN SOUTH AFRICA.—Some accounts of a wonderful meteor, which provided a striking spectacle some time before noon on August 24, are recorded by Mr. Innes in Circular 11 of the Transvaal Observatory. The phenomenon was seen by several persons located near Potchefstroom; but the reports are not strictly in accordance. Mr. Innes suggests the possibility of the several observers having seen portions of a broken-up meteor of such brilliancy as to arrest their attention in full sunlight. Mr. Ingham, chief engineer of the Rand Water Board, estimates that when he saw it the meteor was not more than 400 yards distant, had a head 5 or 6 inches in diameter, and a flame, like that of burning sodium, extending some 12 to 15 feet from the head. No "find" is recorded.

THE PERIOD AND EPOCH OF 68 *u* HERCULIS.—In No. 4526 of the *Astronomische Nachrichten* Dr. Hertzsprung discusses the long series of observations of the variations of 68 *u* Herculis made by J. F. J. Schmidt during 1869–79. He finds for the period 2·051027d., which agrees with the spectroscopic results, and for the commencing epoch of chief minimum, taking the mean of Schmidt's and recent observations, J.D. 2410102·321 M.T. Greenwich. The period shows no apparent variation.

THE ASTRONOMICAL SOCIETY OF BARCELONA.—One of the objects of this society, upon which special stress was laid at its foundation in January, 1910, was the provision of a public observatory where members might meet on fine evenings to study celestial phenomena and to discuss points of astronomical interest. It is pleasant to record that the primary object of the promoters has been realised very unexpectedly, and without cost to the society, in such a manner that within the next few weeks the members will be in absolute possession of a well-equipped observatory. Señor Rafael Patxot y Jubert has offered to present his observatory and instruments to the society, and, needless to say, the offer has been accepted. This establishment, the Observatori Catalá, is situated at San Feliu de Guixols, in the province of Gerona, and in importance stands next to the observatories of Madrid and San Fernando. The whole establishment will be removed immediately to Barcelona, where it will be re-erected on the roof of one of the public buildings.

The instruments include a double equatorial by Mailhat, visual and photographic, with apertures of 8¾ inches and focal lengths of 10 feet and 7 feet 9 inches respectively. A complete set of accessories of precision is included in the gift—spectroscope, micrometer, camera, electric pendulum, and azimuthal theodolite. Annexed to the observatory in its new position will be a room for meetings of the society, library, photographic laboratory, &c. Preparations for the public lunar exhibition, which will be held in Barcelona in May, 1912, are being pushed forward rapidly, and already many promises of assistance have been received from all parts of the world. The exhibition will be held in the University buildings, under the honorary presidency of the rector, Baron de Bonet. The executive council of the society invites the cooperation of seleno-

graphers of all classes in order to make this exhibition, the first of its kind, a success. All communications should be addressed to Señor Don Salvador Raurich, Calle Gran Via Diagonal, 462, 2°, Barcelona, Spain.

THE MAGNITUDES OF EIGHTY-EIGHT STARS IN COMA BERENICES.—In No. 43 (vol. iv., 7) of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowa* Herr Beljawsky gives the resulting magnitudes obtained from the measures of two plates exposed in March last on the Coma Berenices group. The magnitudes were determined by comparison with stars of the Pleiades group, taken on the same plates between exposures on the Coma Berenices group. Comparing his final magnitudes with those obtained by Pickering, M. Beljawsky finds that there is a distinct connection between the difference Beljawsky-Pickering and the spectral class of the stars concerned; the difference increases from class A (0·38) to class K (0·84), and the increase is probably due to a difference in the scale of photographic magnitudes.

THE NEW BOTANICAL LABORATORIES OF THE UNIVERSITY OF MANCHESTER.

THE new botanical laboratories of the University of Manchester were opened by Dr. D. H. Scott, F.R.S., on Friday last, November 3. The new block of buildings consists of four main floors with two mezzanines, and is planned so as to give adequate accommodation for the various branches of botanical science.

For palæobotany, the study of which is so closely associated with the name of the late Prof. Williamson, the first professor of botany of the Owens College, a room is set apart on the ground floor, close to the entrance on the south side of the building; while on the north is a well-lighted laboratory for thirty junior students, connected directly with the larger elementary laboratory in the main building, which is capable of seating forty more students. On the first floor is a large research laboratory, opening into the senior laboratory.

The second floor is devoted entirely to the Cryptogamic Department, which owes its endowment to the munificent legacy of the late Prof. Barker. In addition to providing facilities for researches of a purely scientific nature, the Barker Laboratory will be available for inquiries connected with agriculture, such as investigations into diseases of plants caused by fungi and bacteria.

On the third floor the laboratory for plant physiology occupies the gable end of the building, being designed so as to possess both north light for microscope work and south and west light for experiments requiring direct sunlight. Such experiments can be made either in the laboratory itself or in the greenhouses, which occupy the whole extent of the south front of the top floor. The greenhouses are divided so as to have both a hot and moist and also a cooler and drier portion.

The new botanical block is entirely devoted to laboratory accommodation, and does not contain any lecture-rooms or museum galleries. The facilities for botanical work in the University are added to by the experimental grounds and greenhouses on the Behrens Estate, Fallowfield, which supply both the need of economic botany and zoology. Here experiments in plant breeding have been in progress for some time past, as well as investigations on conditions of cultivation as affecting the development or prevention of certain plant diseases, and the testing of varieties of cultivated plants supposed to be immune to disease.

Photo.] New Botanical Laboratories, University of Manchester. [*E. Vincent Ward.*

At the opening ceremony on Friday, November 3, the Vice-Chancellor (Sir Alfred Hopkinson) welcomed the guests, and after referring to the need there had been for securing adequate accommodation for the teaching of botany in the University, and the steps taken by the council of the University to meet the requirements of the growing department, invited Dr. Scott to open the new building. A ceremonial key was presented to Dr. Scott by the architect, Mr. Paul Waterhouse, and, after the door had been unlocked, the building was declared open, and was inspected by the visitors.

Later in the afternoon Dr. Scott delivered a short address to the friends and students of the University, and spoke

in appreciation of the work of the first professor of botany in the Owens College, the late Prof. Williamson. He directed attention to the fact that during the sixty years which had passed since the foundation of the Owens College there had been only two professors of botany there. Williamson was the first, and the second was the present occupant of the chair, Prof. Weiss. Recalling the facts of Dr. Williamson's life, Dr. Scott reminded his audience of the many-sided character of the former professor of botany, and also specified in detail the work done by Williamson. He took a leading part in bringing home to scientific people the importance of those fossil remains which show structure. Fossil plants are preserved in two quite different ways. On one hand we have the more familiar kind of specimens in the form of casts or impressions which show the external form—often very beautiful—or organisation, but not the structure. On the other are specimens, usually very fragmentary, showing little or nothing of external form, but showing the structure, often beautifully preserved. It was upon the latter form of fossils that all Williamson's later work was done. The fine building now completed is a worthy expression of the progress of the study of botany in Manchester, which has now become one of the greatest centres of botanical teaching in the kingdom.

The ceremony concluded with a vote of thanks to Dr. Scott, proposed by Sir Edward Donner and seconded by Prof. Weiss.

PLAGUE IN EAST ANGLIA.

AFTER a period of quiescence lasting for just over a year, plague has again appeared in East Anglia. Between December 12, 1906, and January, 1907, there were several cases of what was supposed to be pneumonia in two adjoining cottages in the parish of Shotley. There were three cases in one house, two of which were fatal, and five cases in the other, of which four were fatal. It is believed now that all these were cases of pneumonic plague. In January, 1910, two persons died at Trimley, exactly opposite Shotley, on the other side of the River Orwell, from a disease now believed to have been plague. In September, 1910, four persons died in two adjoining cottages in the village of Freston, six miles from Shotley. On October 10 last a seaman was admitted to the sick quarters of the Shotley Royal Naval Barracks, Suffolk, and subsequently developed symptoms of pneumonia. His sputum was examined, and plague bacilli were found. Although there is no certain proof of the source of infection, it is believed he caught the plague from a rabbit he skinned, and that in so doing he cut his finger. This event is not altogether unexpected, as it was known some weeks ago that rats in the Samford Hundred—the district enclosed by the Rivers Orwell and Stour—were again plague-infected; and a vigorous campaign against the rats is being pursued. When the epidemic occurred last year competent authorities warned the Local Government Board of the need for concerted and widespread action for the extermination of rats in the infected district and the delimitation of the infected area.

According to the latest report, the authorities in the Samford district are taking every precaution in the way of destroying rats. As the result of the suggestions of the Local Government Board, it is now proposed that rat-catchers shall be employed in a number of parishes. The public will still receive 2*d.* for every rat killed. Returns of rats killed showed that hundreds were being destroyed in some parishes; in others there were very few to kill. The Local Government Board proposes that concerted action in regard to the plague should be taken by all the neighbouring rural and urban authorities, and it also advises the appointment of a special officer to supervise the destruction of rats. It is to be hoped that, in addition, arrangements will be made for a bacteriological examination of a large proportion of the rats captured, for this procedure is required in order to ascertain the prevalence and area of infection. The rabbits and hares also should be subjected to examination.

CONGRESS OF THE UNIVERSITIES OF THE EMPIRE (1912).

AT a meeting of the Home Universities Committee of the congress, consisting of the Vice-Chancellors of the universities of the United Kingdom and other representatives, held on Saturday, November 4, the programme of subjects for discussion at the congress in July, 1912, was settled.

The meetings of the congress will be held on July, 2, 3, 4, and 5, on four mornings and two afternoons. There will be, in addition, a business meeting.

The subjects for discussion fall under two heads, and are as follows:—

I.—*Universities in their Relation to one another.*

(1) Conditions of entrance to universities and the possibility of equivalence and mutual recognition of entrance tests to degree courses.

(2) Interchange of university teachers; conditions of interchange.

(3) Inter-university arrangements for post-graduate and research students.

(4) Question of division of work and specialisation among universities.

(5) The establishment of a central university bureau; its constitution and functions.

II.—*Universities in their Constitutional Aspects and in their Relation to Teachers, Graduates, and Students.*

(1) The relation of universities to technical and professional education and to education for the public services.

(2) Provision of courses of study and examinations for other than degree students, including university extension and tutorial class work, and specialised courses both of a general and technical character for students engaged in professional, commercial, and industrial pursuits.

(3) The representation of teachers and graduates on the governing body of a university.

(4) Action of universities in relation to the after-careers of their students.

(5) The position of women in universities.

(6) The problem of universities in the East in regard to their influence on character and moral ideals.

(7) Residential facilities, including colleges and hostels.

Upon some of these subjects it is hoped that by cooperation between the universities some action may be possible, *e.g.* such subjects as the extent to which universities may recognise each other's entrance examinations, facilities for post-graduate students from other universities, interchange of professors, &c. There are other questions upon which most, if not all, of the universities will have taken some action and obtained some experience, such as the relationship of universities to colleges associated or federated with them, the position of women in universities, provision for students other than degree students, &c. Upon these questions what is wanted is a summary of the experience of each university presented in a way that will be useful for comparison and will furnish a body of information of permanent value. Accordingly, in addition to the subjects for discussion, other subjects have been selected upon which each of the fifty-one universities is asked to prepare a memorandum. These memoranda will be printed beforehand and issued to members of the congress.

It has been decided that, in addition to the delegates, of which each university is entitled to appoint not more than four, invitations to be present, with the right to speak at the meetings of the congress, shall be issued to a certain number of selected persons. It has been decided that no resolutions will be submitted at the ordinary meetings of the congress, but a special business meeting, confined to delegates of the universities, will be held to deal with executive business. In addition, associate membership of the congress will be open to all who may desire to join on payment of a fee of 10*s.* 6*d.*

BOTANY AT THE BRITISH ASSOCIATION.

TO suit the convenience of members of other sections, the president (Prof. F. E. Weiss) delivered his opening address at twelve noon on Thursday, August 31. The address has already been printed in full in NATURE (September 21, p. 395).

In recent years Section K has frequently shown a

tendency to specialise at particular meetings, *e.g.* in physiology at Dublin. This year an international phytogeographical excursion had been arranged to visit the British Isles during August, and to conclude with the British Association week at Portsmouth. The advent of so many eminent foreign phytogeographers predetermined that the bias of this year's meeting should be ecological. Field excursions, therefore, formed a prominent feature of the programme. The localities visited included Kingley Vale (yew woods), the New Forest (heath, valley-moors, and woodland), Southampton Water (Spartina associations), and Ditcham Park (beech-wood, &c.). In addition to the excursions, there were two discussions and a number of individual papers dealing with phytogeographical subjects. These may be taken first.

The Relation of the Present Plant Population of the British Isles to the Glacial Period.

A joint meeting of botanists, geologists, and geographers was arranged for Monday morning, September 4, the subject under discussion being the relation of the present plant population of the British Isles to the Glacial period.

The discussion was opened by Mr. Clement Reid, F.R.S., who first gave a brief historical summary, and then proceeded to discuss some of the problems which particularly need solution. The first question is, "Are any of our plants survivors that managed to live through the cold of the Glacial period in some warm nook in Britain?" This he answered in the negative, except in the case of certain arctic and alpine species, which thus, he believes, form the oldest element of the British flora. Discussing (with the aid of specially prepared maps) the distribution of ice during the period of maximum intensity of cold, he concluded that the whole of the temperate flora must have been swept away as completely as the celebrated volcanic eruption of 1883 destroyed the vegetation of Krakatoa. Dealing now with the question of reimmigration, he could find no evidence for the existence of post-glacial land-bridges connecting the mainland of Great Britain with either the Scilly Isles, Ireland, or the Continent. Mr. Reid then mentioned some of the well-known peculiarities of distribution in our flora, especially the cases of the Pyrenean, Atlantic, and Germanic elements. Most of the species composing these elements are not really maritime plants, though they have a marked coastal distribution. This he explained as due to their comparatively recent introduction from the nearest continental shores, the lapse of time being such that the slow process of spreading inland has only as yet extended a few miles. Mr. Reid strongly urged the view that chance introduction of seeds (*e.g.* by birds driven by exceptionally strong gales) during thousands of years explains the existing peculiarities of geographical distribution in a way that no changes of sea or land or climate will do.

The president then read a letter which Mr. Reid had received from Dr. A. R. Wallace, F.R.S. Dr. Wallace said that he was firmly convinced that plants had great powers of distribution over the sea, in rare cases even for thousands of miles. Referring to the flora of the Azores, he said "there is absolutely no doubt that the whole of its plants have been gradually introduced during the latter half of the Tertiary period, over a width of ocean of about 1000 miles." But he could not accept Mr. Reid's view that the whole of our flora had been exterminated. "Temperature is only one of many, *very many*, factors that determine the distribution of species; and it is also certain that at the *southern limit* of the ice-sheet the winter temperature may have been quite mild enough to support a large number of our species." Dr. Wallace added that the covering of snow during the winter may have been a compensation for the low temperature.

Dr. Scharff discussed the problem from the zoological point of view, dealing principally with the larger mammals living in Ireland in present and past times. From the evidence of animal remains in the Irish turf, marl and cave deposits, Dr. Scharff maintained that many of the larger herbivores, *e.g.* Irish elk, reindeer, &c., survived in Ireland during the Glacial period. As these animals would require an abundant supply of vegetable food, he differed from Mr. Reid as regards the survival of both animals and plants in Ireland during the cold of the Glacial period.

Dr. O. Stapf, F.R.S., expressed his agreement with the opener's view as to the extinction and reimmigration of the temperate flora of the British Isles, but opposed the view that the curious distribution of the American, Atlantic, and limestone elements is due to chance introduction of seeds from great distances. He described the present distribution of the American and Atlantic plants in question, and pointed out that in both cases there existed (if the different species composing the two groups are considered) such gradations of discontinuity as to connect the extreme cases with cases of almost continuous areas. These extreme instances of discontinuous areas, then, would merely represent the last phase of disintegration. Dr. Stapf concluded by emphasising the importance of preserving and coordinating all records (of rare finds, &c.) which bear on the history of the flora of the British Isles.

Prof. C. Schröter dealt with the theories of Nathorst and Brockman with regard to the post-glacial history of the Swiss flora. He also pointed out that new evidence has accumulated showing the great importance of wind as a factor in the dispersal of plants in the Swiss Alps.

Mr. Wright directed attention to the presence of deeply submerged forests and peat-beds in the southern half of the British Isles. This indicates, though it scarcely proves, that a land connection with the Continent existed in post-glacial times. This connection seems to be demanded for the entry of the larger mammals which have found their way into England and Ireland since the Ice age. The evidence as to the total extinction of all life on Krakatoa has been questioned on the ground that seeds may have been preserved in the old surface deposits beneath the mantle of ash, and subsequently exposed for growth by the rapid formation of rain gullies known to have followed the eruption.

Prof. P. F. Kendall[1] entirely agreed with the conclusions of Mr. Reid, and instanced the case of the Isle of Man as indicating on a small scale what has probably happened in the British Isles as a whole. The Isle of Man presents a great variety of topographical, hydrographic, and other features, and thus offers conditions favourable to the maintenance of an equally varied flora and fauna. But the island is remarkably poor in the number of species of both animals and plants. The explanation seems clear that since the departure of the great ice-sheet the island has been repopulated by plants and animals introduced by chance agencies across the Irish Sea.

Dr. J. E. Marr, F.R.S.,[1] said it is generally admitted that after the great Ice age a period occurred which was marked by widespread steppe conditions. It is to be expected that survivals of this period would persist in areas not now under steppe conditions. He suggested that a case of such persistence may be found in a group of xerophytes growing on the Brecklands of North Suffolk and South Norfolk.

Prof. O. Drude pointed out that in attempting to solve a problem of this nature it was necessary to consider, not Great Britain alone, but also the whole of middle Europe. During what is known as the Baltic Ice age, *Picea excelsa*, and even Hymenophyllum, survived in Saxony. It is not impossible, therefore, that temperate forms, mingled with boreal, may have survived in the south of England.

Dr. F. J. Lewis was of opinion that the evidence of submerged peat deposits and buried forests pointed to considerably greater changes of level than those allowed by Mr. Reid. He also thought that the conditions of Krakatoa were so different from those of Britain during post-glacial times that comparisons between the two were unsafe.

Dr. C. H. Ostenfeld thought that the importance of "nunataks" has been overestimated. It is very difficult to be certain of whether a mountain summit has been glaciated or not. Dr. Ostenfeld maintained that the bulk of the temperate British flora had returned by means of a land-bridge, though he admitted that a few of the Atlantic and the two American species had probably arrived by chance.

Mr. E. A. N. Arber believed that land connections existed

[1] Prof. Kendall and Dr. Marr sent written communications, as they were unable to be present.

between England and France, both before and after the main period of glaciation.

Dr. C. E. Moss thought it a mistake to confine attention to the local "Lusitanian" species of west Ireland and south-west England. Belonging to the same distributional type are a number of halophytes, *e.g. Limonium reticulatum, Suaeda fruticosa*, &c., which in Britain are limited to the south and east coasts. These probably migrated from south Europe to Britain *via* the west coast of France. Being salt-marsh plants, their seeds are probably carried by ocean drifts. This may explain their absence from the west coast of Britain, as the trend of the currents is in an easterly direction.

Mr. G. Claridge Druce contributed to the discussion a statement of the appearance of species in isolated spots, *e.g. Scirpus maritimus* in Berkshire, and suggested that these were examples of chance dispersal by wind or birds. The same was probably true of the rapid spread of *Crepis taraxacifolia* over Midland England during the last twenty years.

Mr. Clement Reid briefly replied, and still adhered to his main contentions. With regard to the possible survival of plants in Britain, not only was the land itself glaciated, but the surrounding sea was intensely cold. On the subject of post-glacial connections with the Continent we cannot speak with absolute certainty, but he could find no evidence of sufficiently great oscillations of level to allow of their existence. The Irish peat-bog mammals referred to by Dr. Scharff are all good swimmers, and could quite well have crossed a narrow strait. This concluded one of the best discussions which has been held under the auspices of Section K.

The Principles of Constructing Phytogeographical Maps.

A second discussion was arranged for Tuesday morning, September 5, on the principles of constructing phytogeographical maps.

Dr. C. E. Moss, who opened this discussion, briefly traced the history of the recently issued British vegetation maps, and compared them with those produced on the Continent. Dr. Moss pointed out the uses, and also the limitations, of such maps. He emphasised the fact that vegetation maps are just as important as geological maps. Yet the latter are prepared and published by a Government department, while the former are left to the initiative of private individuals, who at present experience great difficulty in securing the publication of their work.

Prof. C. Schröter, who exhibited a fine collection of phytogeographical maps he had brought with him from Switzerland, classified such maps as follows:—(1) autochorological maps, which show the distribution of systematic units (genera, species, &c.); (2) synchorological or formation maps, illustrating the distribution of plant formations; (3) epiontological or historical maps, giving the distribution of floral elements and the history of their immigration; and (4) floristic maps, showing the division of a country into botanical regions.

Prof. O. Drude laid down certain important principles which should be observed in constructing phytogeographical maps. *E.g.* the colour scheme should be such as not to interfere with the general topography, which should be clearly distinguishable even in vegetation maps. Prof. Drude then proceeded to criticise the British maps in respect to certain technical details. He was followed by

Mr. A. G. Tansley, who pointed out that most of Prof. Drude's criticisms had been anticipated by the committee for the survey and study of British vegetation. Many improvements had been adopted in the later maps which, as Dr. Moss had pointed out, still awaited publication.

Dr. E. Rübel distributed copies of his vegetation map of the Bernina district in the Engadine. This map shows what can be done in the way of indicating on a single map such things as, *e.g.* in the case of woodland, not only the distribution of forest, but also the proportion of the more important trees, the types of undergrowth, &c.

Ecological Papers.

Thursday was largely devoted to individual ecological papers.

Prof. F. W. Oliver, F.R.S., read a paper on the life-history of a shingle bank, in which he dealt with the conditions under which plants exist on maritime shingle beaches. Most shingle banks are very mobile. This is due partly to the action of storm waves and partly to undermining by percolating sea water. A passive condition is indicated by the presence of lichens, &c. The origin of the soil occupying the interstices of the shingle was discussed. The most important source of this appears to be the drift on the lee side of the bank. This gradually becomes incorporated with the shingle during the slow landward march of the latter. Considered as a plant habitat, a very remarkable feature of a shingle bank is the rich supply of water with which it is provided, even in its upper zones. This feature requires further investigation.

Prof. C. Schröter next gave an illustrated account of the Swiss National Park and its flora. There are in Switzerland at the present time four organisations working for the preservation of natural and prehistoric monuments. One of the results of this movement has been the establishing of a National Park, or reservation. This is planned to cover an area of 200 square kilometres, about 90 of which have already been acquired.

Prof. J. Massart, in a very interesting paper on phytogeography as an experimental science, strongly urged the necessity for experiment as a method of attacking problems of plant geography. One example mentioned was the case of certain moorland plants (*e.g. Calluna vulgaris*) which flourish in such an unusual habitat as the limestone pavements of west Ireland. Why are these calcifuge species able to grow on limestone in Ireland? Is it because the climate is sufficiently favourable to enable them to withstand the deleterious effects of the calcareous soil? Or because the limestone forms of these species are biologic races, analogous to the cases of some parasitic fungi? Or is it that certain competing species are absent from Ireland? This and many similar problems can only be solved by direct experiment.

The afternoon session was opened by Prof. H. C. Cowles, who gave an illustrated account of a fifteen-year study of the advancing sand-dunes of Lake Michigan. These dunes are frequently 65 metres in height, and travel so rapidly that few of the antecedent plants are able to survive. Curiously enough, those which do so are not the more xerophytic species, but swamp plants and mesophytes, such as Cornus, Salix, Populus, &c. The survival of these plants depends on their capacity to elongate and produce new adventitious roots rapidly.

Miss S. M. Baker, in describing the brown seaweeds of a salt marsh, stated that all the brown seaweeds occurring near high-water level on rocky shores are capable of giving rise to marsh forms. Such marsh forms are frequently characterised by a spiral twisting of the thallus.

Prof. R. H. Yapp next discussed the causes which determine the formation of hairs and palisade cells in plants. The results of many previous experiments show that, in general, palisade tissue and the hairs on aërial shoots are best developed under external conditions which either favour transpiration or hinder absorption. The conclusion was arrived at that the initial stimulus leading to the development of these special cells is connected with a diminished water supply. But turgidity is a necessary condition for the actual growth of the cells. Thus periodic fluctuations in the turgor of the cells concerned, such as will frequently occur during the alternation of day and night, may play an important part.

Dr. F. J. Lewis read a paper on the forest stages represented in the peat underlying the moorlands of Britain. The author's earlier researches on this subject are well known. In this paper he gave some of the results of his more recent work in the Hebrides and elsewhere. The paper was well illustrated by lantern-slides.

A paper was communicated by Miss L. Baker and Mr. B. W. Baker on the plant associations of the district round Macclesfield.

Mr. W. B. Crump, in an interesting paper on the water-content of acidic peats, dealt with the question of the water supply of plants growing on acid soils. Mr. Crump emphasised the importance of considering the humus- as well as the water-content when analysing these soils. He contended that if the results of such analyses be expressed by the ratio water-content/humus-content some indication is obtained of the amount of water available for absorption by the plant.

A further communication by the same author described some experiments on the wilting of moorland plants, in which he attempted to determine directly the physiological water-content of moorland soils.

Palaeobotanical Papers.

Friday morning was chiefly occupied by the communication of palæobotanical papers.

Miss M. Kershaw described the structure and development of the ovule of a cycad, *Bowenia spectabilis*, dealing particularly with the complicated pollen-chamber of this genus. Miss Kershaw, and also several speakers in the discussion which followed, compared the ovule with certain fossil seeds, especially Trigonocarpon.

Dr. M. J. Benson read a paper on a new type of synangium, which she attributed to *Heterangium Grievii*. The author maintained that the discovery of this early synangium affords support to the synangial theory of the seed.

Dr. D. H. Scott, F.R.S., who followed, dealt with the structure and relationships of a rare Palæozoic fern, *Zygopteris Grayi*. This species possesses a five-rayed stellate stele, with internal xylem consisting of narrow tracheides embedded in parenchyma. Dr. Scott is inclined to regard this type of stele as an elaborated protostele rather than a condensation of a more complex vascular system.

Mr. H. Hamshaw Thomas gave a general account of recent researches on the Jurassic plants of Yorkshire. Amongst other things described were several new fossils found by Mr. Thomas himself, *e.g.* a new Bennettitalian "flower" with microsporophylls as well as ovules, and a fruit-like body containing seeds. To the latter he has given the name Caytonia. The discussion which followed centred mainly about the probable nature of this apparent fruit.

Prof. A. C. Seward, F.R.S., gave an account of the structure of a petrified Williamsonia collected by Hugh Millar in north-east Scotland, and figured by him in "The Testimony of the Rocks." The specimen, of which sections have been cut by permission of the director of the Royal Scottish Museum, Edinburgh, consists of a central conical axis bearing immature interseminal scales and seeds, the whole being enclosed by linear bracts bearing numerous unicellular hairs. The structure of the plant will be fully described in a forthcoming paper. In commenting on this paper in the discussion, Dr. Scott remarked that we know nothing at present about the young stages of the ovules in any Bennettitales.

From the examination of serial sections through entire boulders of calciferous sandstone from Pettycur, Miss T. Lockhart was led to results which confirm Dr. Gordon's view that petrifaction of the plant remains in these boulders occurred in thermal pools.

Cytological Papers, &c.

Cytological papers, &c., were taken on Friday afternoon. The first paper was one contributed by Dr. A. A. Lawson, on nuclear osmosis as a factor in mitosis. The results obtained by the author are at variance in several respects with those of previous observers. He finds that the nuclear membrane does not break down and disappear, but persists as a permeable plasmatic membrane. During mitosis, the nuclear sap diffuses through this membrane, which consequently closes in around the chromosomes, the nuclear cavity becoming much reduced. The author further maintains that the spindle threads are merely a drawing out of the cytoplasmic reticulum by the receding membrane. They thus represent lines of tension in the cytoplasm. They neither invade the nuclear cavity nor aid in drawing the daughter chromosomes to the poles of the spindle.

Dr. H. C. I. Fraser next gave a paper on the longitudinal fission of the meiotic chromosomes in *Vicia Faba*. This paper was a continuation of one communicated at the Sheffield meeting. The chromosomes undergo longitudinal fission during the telophase of the last archesporial division. The V-shaped chromosomes undergo a second longitudinal fission at the poles of the heterotype spindle. Both fissions are recognisable until the chromosomes pass on to the homotype spindle. The second fission disappears during metaphase, but is again visible when the chromosomes come into contact at the poles.

Mr. T. G. B. Osborn gave an account of the life-cycle and affinities of the Plasmodiophoraceæ. A cytological investigation of the life-history of *Spongospora subterranea* showed a very close similarity to that described for certain genera of the Plasmodiophoraceæ by Maire and Tison. The chief difference was that in Spongospora a fusion of nuclei in pairs occurred after the akaryote condition.

Mr. A. S. Horne followed with a paper on somatic nuclear division in *Spongospora Solani*, in which a peculiar form of karyokinesis was described as occurring during the early stages of the life-history.

The proceedings on Friday were terminated by a paper from Mr. A. E. Lechmere, on some West African fungi. Amongst others, a series of interesting forms were isolated which apparently belong to a new genus of Pyrenomycetes. Mr. Lechmere illustrated his paper by photographs and also living cultures.

The Semi-popular Lecture

The semi-popular lecture this year was given by Dr. Francis Darwin, F.R.S., the subject being "The Balance-sheet of a Plant." The lecture was exceedingly interesting and full of apt illustration, and was much appreciated by a crowded audience. Dr. Darwin explained that the "balance-sheet" of the title referred to the water supply of the plant. The lecture cannot be fully noticed here, but it may be mentioned that Dr. Darwin adduced some convincing experiments of his own to show that Lloyd's contention that transpiration is not regulated by movements of the stomata is contrary to fact.

Miscellaneous Papers.

Wednesday morning was occupied by a series of miscellaneous papers and reports of committees.

Mr. Mangham read a paper in which he gave the results of further work on the translocation of sugars by sieve-tubes. The investigation had been extended to Laminaria, and crystalline osazones were found in the cortical cells, sieve-tubes and hyphæ of two species of this genus, especially at the time of formation of the new lamina in *L. digitata*.

Prof. W. B. Bottomley dealt with the structure and functions of the root-nodules of *Myrica Gale*. He concluded that these nodules are concerned with the assimilation of atmospheric nitrogen, as are those of Cycas, Alnus, and other plants.

Another paper by the same author described some experiments on the effect of bacteriotoxins on the growth of plants. An aqueous extract of manure was found to have an injurious effect on the germination of seeds and on the subsequent growth of the seedlings. The harmful effect (which could be prevented by heating the extract) appeared to be due to bacteriotoxins, probably of the nature of toxalbumoses.

Mr. A. S. Horne suggested that the Cornaceæ are polyphyletic. This hypothesis is the result of a comparative study of the flower in the Cornaceæ and allied orders. The uniovular condition and other resemblances in the order are regarded merely as cases of parallelism, the evolutionary history being different in different cases.

Sir Daniel Morris, F.R.S., directed attention to the recent and rapid spread of *Oidium euonymi-japonicae* in southern England, and urged that steps should be taken to prevent the mischief caused by this pest.

Owing to the limited time available, and the absence of the authors, the following papers were taken as read:—the chromosomes of the hybrid *Primula kewensis*, by Miss L. Digby; and a note on the flora of Shetland, with some reference to its ecology, by Mr. W. West.

Reports of Committees.

Reports were presented by five research committees:—(1) The experimental study of heredity. The following summary of the report will indicate the scope of the work carried on. The experiments on the inheritance of double flowers have been continued. In the case of stocks, the results have now shown that this character is inherited in accordance with definite, though somewhat complicated, laws. Similar experiments have also been carried out on several other genera, chiefly biennials (carnation, hollyhock, &c.). These have now been carried to the third

generation. Investigations are being continued on the inheritance of a mutation in the foxglove. Investigations into the inheritance of colour in *Primula sinensis* have been carried further, and attention has been paid to the genetics of parti-coloured and flaked types. The inheritance of an abnormal type of flower in the wallflower is being investigated, and experiments are also being made with a putative hybrid between two species of Taraxacum. Mrs. Thoday has continued her experiments on the nature and inheritance of the yellow tinge in the sweet pea. (2) Botanical photographs. A second list of photographs collected by the committee has been printed and distributed to the botanical members of the association. By this means it is hoped that the collection will become more widely known, and used for teaching and other purposes. (3) A botanical, zoological, and geological survey of Clare Island. It is hoped that the survey will be completed by the end of the present year. (4) The structure of fossil plants. (5) On a national flora.

ANIMAL SANCTUARIES IN LABRADOR.[1]

A SANCTUARY may be defined as a place where man is passive and the rest of nature active. Until quite recently Nature had her own sanctuaries, where man either did not go at all or only as a tool-using animal in comparatively small numbers. But now, in this machinery age, there is no place left where man cannot go with overwhelming forces at his command. He can strangle to death all the nobler wild life in the world to-day. To-morrow he certainly will have done so unless he exercises due foresight and self-control in the meantime. There is not the slightest doubt that birds and mammals are now being killed off much faster than they can breed. And it is always the largest and noblest forms of life that suffer most. The whales and elephants, lions and eagles, go. The rats and flies, and all mean parasites, remain. This is inevitable in certain cases. But it is wanton killing off that I am now describing. Civilised man begins by destroying the very forms of wild life he learns to appreciate most when he becomes still more civilised. The obvious remedy is to begin conservation at an earlier stage, when it is easier and better in every way, by enforcing laws for close seasons, game preserves, the selective protection of certain species, and sanctuaries. The mere fact that man has to protect a sanctuary does away with his purely passive attitude. Then he can be beneficially active by destroying pests and parasites, like bot-flies or mosquitoes, and by finding antidotes for diseases like the epidemic which periodically kills off the rabbits, and thus starves many of the Carnivora to death. But, except in cases where experiment has proved his intervention to be beneficial, the less he upsets the balance of nature the better, even when he tries to be an earthly Providence.

The strongest of all arguments is that sanctuaries, far from conflicting with other interests, actually further them. But unless we make these sanctuaries soon we shall be infamous for ever as the one generation which defrauded posterity of all the preservable wild life that nature took a million years to evolve into its present beautiful perfection. Only a certain amount of animal life can exist in a certain area. The surplus must go outside. So sanctuaries are more than wild "zoos"; they are overflowing reservoirs, fed by their own springs, and feeding streams of life at every outlet. I might mention many instances of successful sanctuaries, permanent or temporary, absolute or modified—the Algonquin, Rocky Mountains, Yoho, Glacier, Jasper and Laurentides in Canada; the Yellowstone, Yosemite, Grand Cañon, Olympus, and Superior in the United States; with the sea-lions of California, the wonderful revival of ibex in Spain and deer in Maine and New Brunswick, the great preserves in Uganda, India, and Ceylon, the selective work of Baron von Berlepsch in Germany, the curious result of taboo protection up the Nelson River, and the effects on seafowl in cases so far apart in time and space as the Guano Islands under the Incas of Peru, Gardiner Island in the United States, or the Bass Rock off the coast of Scotland.

Yet I do not ignore the difficulties. First, there is the universal difficulty of introducing or enforcing laws where there have been no operative laws before. Next, there is the difficulty of arousing public opinion on any subject, however worthy, which requires both insight and foresight. Then we must remember that protected species increasing beyond their special means of subsistence have to seek other kinds of food, sometimes with unfortunate results. And then there are the several special difficulties connected with Labrador.

But in spite of all difficulties, I firmly believe that Labrador is by far the best country in the world for the best kinds of sanctuary. Labrador decidedly improves on acquaintance. The fogs have been grossly exaggerated. The Atlantic seaboard is clearer than the British Isles, which, by the way, lie in exactly the same latitudes. And the Gulf is far clearer than New Brunswick, Nova Scotia, and the Banks. The climate is exceptionally healthy, the air a most invigorating tonic, and the cold no greater than in many a civilised northern land. Besides, there is a considerable range of temperature in a country the extreme north and south of which lie 1000 miles apart, one in the latitude of Greenland, the other in that of Paris.

Most of Labrador is a rocky tableland, still rising from the depths, with some old beaches as much as 1500 feet above the present level of the sea. The St. Lawrence seaboard is famous for its rivers and forests. The Atlantic seaboard has the same myriads of islands, is magnificently bold, is pierced by fiords unexcelled in Norway, and crowned by mountains higher than any others east of the Rockies. This vast country is accessible by sea on three sides, and will soon be accessible by land on the fourth. It lies directly half-way between Great Britain and our own North West, and is 1000 miles nearer London than New York is. Its timber, mines, and water-power will be increasingly exploited. It should also become increasingly attractive to the best type of tourist, naturalist, and sportsman.

The fauna is much more richly varied than people who think of Labrador as nothing but an Arctic barren are inclined to suppose. The fisheries have been known for centuries, especially the cod, which has a prerogative right to the simple word "fish." There are herring and lobsters in the Gulf, plenty of salmon and trout in most of the rivers, winninish in all the tributary waters of the Hamilton, as well as in Lake St. John, whitefish in the lakes, and so forth. Then the stone-carrying chub is one of the most interesting creatures in the world.

Yet I must not forget the "flies"—who that has felt them once can ever forget them? The bot-fly infests the caribou, and will probably infest the reindeer. The black-fly and mosquito attack both man and beast in maddening millions.

Labrador has more than 200 species of birds, from humming-birds and sanderlings to eagles, gannets, loons, and herons.

Both the land and sea mammals are of great importance. Several whales are well known. The right whale is almost exterminated, but the Greenland, or bow-head, is found along the edge of the ice in all Hudsonian waters. The pollock is rare, and the sperm, or cachalot, as nearly exterminated as the right. But the little-piked, or *rostrata*, is found inshore along the north and east, the bottle-nose on the north, the humpback on the east and south, and the finback and sulphur-bottom are common and widely distributed, especially on the east. The little white whale, or "white porpoise," is fairly common all round; the killer is widely distributed, but most numerous on the east, where the narwhal is also found. The harbour and striped porpoises, and the common and bottle-nosed dolphins, are chiefly on the east and south. There are six seals, the harbour, ringed, harp, bearded, grey, and hooded. The walrus, formerly abundant all round, is now rarely seen except in the far north, where he is fast decreasing.

Moose may feel their way in by the south-west to an increasing extent, and might possibly be reinforced by the

[1] From an address presented by Lieut.-Colonel William Wood before the second annual meeting of the Commission on Conservation held at Quebec.

Alaskan variety. Red deer might possibly be induced to enter by the same way in fair numbers over a limited area. The woodland caribou is almost exterminated, but might be resuscitated. The barren-ground caribou is still plentiful in the north. Their tame brother, the reindeer, is being introduced as the chief domestic animal of eastern Labrador, with apparently every prospect of success. Beaver are fairly common and widely distributed in forested areas. Other rodents are frequent—squirrels, musk-rats, mice, voles, lemmings, hares, and porcupines. There are two bats. Black bears are general; polars in the north. Grizzlies have been traded at Fort Chimo in Ungava, but they are probably all killed out. The lynx is common wherever there are woods. There are two wolves, arctic and timber, the latter now rare in the south. The Labrador red fox is very common in the woods, and the "white," or arctic fox, in the barrens and further south on both coasts. The "cross," "silver," and "black" variations of course occur, as they naturally increase towards the northern limits of range. The "blue" is a seasonal change of the "white." The wolverine and otter are common. The skunk is only known in the south-west. The mink ranges through the southern third of the peninsula. The Labrador marten, or "sable," is a subspecies, generally distributed in the forested parts, like the weasel. The "fisher," or Pennant's marten, is much more local, ranging only between the "North Shore" and Mistassini.

When we consider how easily wild life can be preserved in Labrador, and how beneficial its preservation is to all concerned, we can understand how the wanton destruction going on there is quite as idiotic as it is wrong.

Take "egging" as an example. The Indians, Eskimos, and other beasts of prey merely preserved the balance of nature by the toll they used to take. No beast of prey, not even the white man, will destroy his own stock supply of food. But with the nineteenth century came the white-man market "eggers," systematically taking or destroying every egg in every place they visited. Halifax, Quebec, and other towns were centres of the trade. The "eggers" increased in numbers and thoroughness until the eggs decreased in the more accessible spots below paying quantities. But other egging still goes on unchecked. And this is on the St. Lawrence, where there are laws and wardens and fewer fishermen. What about the Atlantic Labrador, where there are no laws, no wardens, many more fishermen, and ruthless competitive egging between the residents and visitors? Of course, where people must egg or starve there is nothing more to be said.

And it is just as bad with the birds as with the eggs. A schooner captain says. "Now, boys, here's your butcher shop: help yourselves!" and this, remember, is in the brooding season. Not long ago the men from a vessel in Cross Harbour landed on an islet full of eiders, and killed every single brooding mother. In the summer of 1907 an American millionaire's yacht landed a party who shot as many brooding birds on St. Mary Island as they chose, and then left the bodies to rot and the broods to perish. That was, presumably, for sport. Deer were literally hacked to pieces by construction gangs on new lines last summer. Dynamiting a stream is quite a common trick wherever it is safe to play it. Harbour seals are wantonly shot in deep fresh water where they cannot be recovered, much as seagulls are shot by blackguards from an ocean liner.

And the worst of it is that all this wanton destruction is not by any means confined to the ignorant or those who have been brought up to it.

We have had our warnings. The great auk and the Labrador duck have both become utterly extinct within living memory. The Eskimo curlew is decreasing to the danger point, and the yellowlegs is following. The lobster fishing is being wastefully conducted along the St. Lawrence; so, indeed, are the other fisheries. Whales are diminishing. The walrus is exterminated everywhere in Labrador except in the north. The seals are diminishing. The woodland caribou has been killed off to such an extent as to cause both Indians and wolves to die off with him. The barren-ground caribou is still plentiful, though decreasing.

All the sound reasons ever given for conserving other natural resources apply to the conservation of wild life—and with threefold power. When wild life is squandered it does not go elsewhere, like squandered money; it cannot possibly be replaced by any substitute, as some inorganic resources are: it is simply an absolute dead loss, gone beyond even the hope of recall. How is Labrador to be brought under conservation, before it is too late, in the best interests of the five chief classes of people who are concerned already, or will be soon? The five great interests are those of (1) food; (2) business; (3) the Indians and Eskimos; (4) sport; and (5) the zoophilists, by which I mean all people interested in wild animal life, from zoologists to tourists.

The resident population is so sparse that there is not one person for every 20,000 acres; and most of these people live on the coast. Consequently, the vast interior could not be used for food supplies in any case.

Business is done in fish, whales, seals, fur, game, plumage, and eggs. The fish are a problem apart. But it is worth noting that uncontrolled exploitation is beginning to affect even the countless numbers in certain places. No one wants his business to be destroyed. But if Labrador is left without control indefinitely every business dealing with the products of wild life will be obliged to play the suicidal game of competitive grab until the last source of supply is exhausted, and capital, income, and employment all go together.

The Eskimos are few, and mostly localised. The Indians stand to gain by anything that will keep the fur trade in full vigour, as they are mostly hunters and trappers. Restriction on the number of skins, if that should prove necessary, and certainly on the sale of all poisons, could be made operative.

Sport should have a great future in Labrador. The extension and enforcement of proper game laws would benefit sport directly, while indirectly benefiting all the other interests.

The zoophilist class seems only in place as an afterthought. But I am convinced that it will soon become of at least equal importance with any other. All the people, from zoologists to tourists, who are drawn to such places by the attraction of seeing animal life in its own surroundings already form an immense class in every community; and it is a rapidly increasing class.

Partly because Quebec has taken the lead in legislation, and partly because an ideal site is ready to hand under its jurisdiction, I would venture to suggest the immediate establishment of an absolute sanctuary for all wild birds and mammals along so much of the coast as possible on either side of Cape Whittle. The best place of all to keep is from Cape Whittle eastward to Cape Mekattina, sixty-four miles in a straight line by sea. Cape Whittle is a great landmark for coasting vessels and for the seal herds as well. A refuge for seals is absolutely necessary to preserve their numbers and the business connected with them. The case of the birds is quite as strong, and the chance of protection by this sanctuary much greater.

There is the further question—affecting all migratory animals, but especially birds—of making international agreements for their protection. There are precedents for this, both in the Old World and in the New: and, so far as the United States is concerned, there should be no great difficulty. Immediate steps should be taken to link our own bird sanctuaries with the splendid American chain of them which runs round the Gulf of Mexico and up the Atlantic coast to within easy reach of the boundary line. Corresponding international chains up the Mississippi and along the Pacific would be of immense benefit to all species, and more particularly to those unfortunate ones which are forced to migrate down along the shore and back by the middle of the continent, thus running the deadly gauntlet both by land and sea.

Inland sanctuaries are more difficult to choose and manage. A deer sanctuary might answer near James Bay. Fur sanctuaries must also be in some fairly accessible places on the seaward sides of the various heights-of-land, and not too far in. The evergreen stretches of the Eastmain River have several favourable spots. What is needed most is an immediate examination by a trained zoologist. The existing information should be brought together and carefully digested for him in advance.

THE PRESENT POSITION OF ELECTRIC STEEL-MELTING.[1]

THE melting of steel by means of electricity has passed the merely experimental stage and become one of the commercial processes by means of which steel is manufactured for the market. It is not correct to say that it has emerged from the experimental stage, however, as not only this process of steel-making, but most other processes, are being continually experimented with and the results compared with one another by up-to-date and vigorous firms, not only for the new conditions that are always arising, but also for old and well-tried conditions.

A new demand arises or repeat orders come in, and the manufacturer must ask himself what kind of steel will best suit the purpose at the present time. Will Bessemer or open-hearth steel be most suitable to satisfy the demand, price, quality, and all other matters considered, and must it be acid steel or will basic do, or is it necessary or desirable to use crucible steel, or perhaps this new electric steel, to maintain or increase his profit or his reputation for certain goods? These are problems of daily occurrence; and although the difficulties of the manufacture of electric steel by various processes have been fairly well overcome, so far as making it to specification of chemical composition and mechanical tests is concerned, it is in connection with such questions as are indicated in the previous sentence that it is still in the earlier experimental stage. All other processes, however, are more or less under such trials until they become extinct. The point need not be laboured, for many examples will come to the mind at once, such as the comparative merits for various purposes of Swedish-Lancashire and Walloon iron, of mild steel and wrought iron, of acid and basic steel, and so on. The general impression gathered from much conversation with users is that the arc-furnace product from slightly impure materials, purified to Swedish standard, just about takes its place by Swedish open-hearth and Bessemer steels, and that the induction-furnace product skilfully made from pure materials equals anything but the very highest qualities of crucible steels. These are very general statements, but they represent the writer's present more or less intuitive opinions, and only time can determine whether they are correct; for the fact that steels are of certain chemical compositions and give certain mechanical tests is not a final judgment, but the quality and length of service given in actual use. The special feature of the Héroult and Röchling-Rodenhauser types is that with an oxidising purification phosphorus can be eliminated to almost any extent that will pay, and after removing the slag, and forming another, by a reducing purification sulphur can similarly be removed.

The Kjellin induction furnace acts as a melter of materials much after the manner of the crucible, and has one advantage over the crucible in that there is no absorption of sulphur during melting. Recent experiments with covering slags specially calculated by the writer to give a minimum of change in composition during melting show, according to a student's preliminary analysis, compositions in the ingots practically equal to those by calculation from the constituents, a result better than expected, but still requiring thorough checking. The results at least serve as a text for one fact that must never be forgotten. The electric furnace, of whatever design, will not make good steel automatically. The same metallurgical skill required by the older processes must be expended on the proper killing and finishing of the steel by whatever type of electric furnace it is being melted, and the fact that in electric as in other furnaces bad steel may be made from good materials increases the difficulties of finding the exact place of any steel in the world's work. Several cases where the electric steel has been found unsuitable, especially in the earlier days, have been investigated, and it has been found that the steel has been wrongly made. In other cases no such explanation could be given. Recently I had a long talk with a man using large quantities of electric steel; he could get great purity, but no better mechanical tests; yet he found the electric steel gave a better life than his former steel, and so he used it. Here again another difficulty comes in as represented by the fact that I did not think his ordinary steel was specially well made.

[1] Report presented at the Portsmouth meeting of the British Association (Section B) by Prof. Andrew McWilliam.

One point of importance is that this production of electric steel has introduced a new competitor into the field by giving great impetus to the use of what is sometimes called white coal, namely, the great waterfalls, mostly far removed from coal; and much energy is now being used that formerly ran to waste, whilst the successful application of electric power to the production of charcoal pig-iron allows of a much reduced consumption of charcoal. The rapidly increasing price of charcoal in Sweden, owing, among other causes, to so much of the wood being used for making wood pulp for paper-making, is quite a serious situation, which this application of electric power may help to relieve.

The whole subject of electric iron-smelting and electric steel-melting is attracting much attention. Several books have been published on electric furnaces; and during 1909 and 1910 many interesting articles on the subject have appeared in the technical journals, and many papers have been read before the Iron and Steel Institute. At the autumn meeting of 1909 Mr. C. A. Ljungberg gave a paper on production of iron and steel by electric-smelting processes. He mentioned the Kjellin electric induction furnace at Gysinge, with which the writer had the pleasure of making with Mr. E. C. Ibbotson a full week's trial, as being still in work, making tool steel, special steels, self-hardening and high-speed steels, and others such as nickel and chromium steels. The paper dealt more in detail, however, with the successful experiments on smelting pig-iron at Domnarfvet by electrical means, and the resulting saving in the proportion of charcoal used.

It will be only necessary merely to touch upon the various principles used in the construction of electric furnaces, as these are found in text-books and in the Proceedings of the Iron and Steel Institute. Having obtained an electric current, its energy may be converted into heat by putting a suitable resistance in its path, and the heat may be concentrated at any part of the circuit by making the resistance of other parts small in comparison. If the resistance be a solid or a liquid, then it is called resistance-heating; if a gas, arc-heating. If the liquid through which the current passes is decomposed by the current so that one kind of matter goes to one pole and another kind to the other pole, the liquid is called an electrolyte.

Varieties of Electric Furnaces.

The Stassano furnace is an independent arc furnace. Three carbon electrodes are used, between which arcs play, and the heat from the arc is merely used for heating the charge, partly by direct radiation and partly by reflection from the dome of the furnace.

The Héroult steel-melting furnace is a direct-arc type in which the charge forms one pole of the arc. Two vertical carbon electrodes come through the roof of the furnace and two arcs play, one between each electrode and the molten metal or slag beneath it, the current passing from one electrode through the metal or slag and up through the other electrode.

The Girod furnace, like the Héroult, is a direct-arc furnace, but one or more electrodes of like polarity are maintained above the bath, and soft steel pieces embedded in the hearth of the furnace are in direct contact with the molten metal for the negative electrode. These lower pole-pieces are water-cooled. Large quantities of ferro-silicon, ferro-chrome, &c., as well as of ordinary carbon and special steels, are made in this furnace.

The Keller steel furnace is a direct-arc furnace, very much like the Héroult, only instead of two electrodes coming down into one cavity they come into separate cavities, which are joined by the molten material of the bath.

The Grönwall is of the arc type, and the current enters by two electrodes through the roof; and when once the bath is heated, so that the lining becomes a conductor, the current from both electrodes passes through the lining to a graphite block underneath, and hence to a common wire.

The Nathusius, like the Grönwall, is a combined arc and resistance furnace. It contains three vertical carbon electrodes, arranged at the apices of an equilateral triangle,

and three steel electrodes similarly arranged in the bottom of the furnace, but covered by refractory material. Three-phase current is used, and it is claimed that the current flows from one top electrode to the others, from one bottom electrode to the others, and from each top electrode to each bottom electrode.

Kjellin Induction Furnace.—In this furnace, an example of which is in the metallurgical laboratory of the University of Sheffield, and was shown working to the members of the British Association, the metal charge is placed in an annular hearth, almost like a steel-melting crucible in section, but in the form of a ring. The primary coil of twenty-four turns is placed in the centre round a core of laminated iron. The bath or ring of metal acts as a secondary circuit of a single turn, and the heat is thus produced in the charge itself without contact with electrodes. In the Frick furnace the primary coil is above the crucible, and in the Colby round the outside of the crucible.

The Röchling-Rodenhauser furnace is based on the Kjellin principle, but has an important addition. In its simplest form, for single-phase current, there are two grooves, or heating channels, corresponding to the annular crucible of the Kjellin, but these join to a central open-hearth, the whole hearth forming a kind of figure 8. In the central open-hearth all the distinctly metallurgical operations take place, so that this form can be used for refining work, for which the Kjellin is not very suitable. Not only so, but a distinct secondary winding is provided in which a secondary current is induced, and these windings are joined to steel terminal plates which are embedded in the refractory material of the furnace at the ends of the central hearth. At high temperatures the refractory material becomes a conductor of electricity, and thus the currents induced pass through the bath in the central hearth, heating it still further.

There are many others, some only on paper; but these are the principal varieties that have been tried with any considerable degree of success. The loss in melting is an important point, and I am informed that this amounts to about $1\frac{1}{2}$ per cent. in the Kjellin, about 4 to 5 per cent. in the Röchling-Rodenhauser, and 7 to 8 per cent. in arc furnaces.

In considering the present position of the electric steel-melting industry regard must be had to the numbers and capacities of the various types of furnaces in work, not in work, and being built, although a complete survey should also take account of the nature and quality of the materials being made, for a furnace making a ton of high-speed steel should obviously be credited with more importance in the commercial world than one making a ton of steel for rails. The progress in numbers and capacities and in output should also be considered. So far as one could ascertain, about June, 1910, there were about 118 furnaces of all types, of which 70 were in use, 10 not working, and 38 being built. There were 77 of the arc furnaces recorded, of which 29 were credited as Héroult, 17 Girod, 13 Stassano, 6 Keller, and 9 others; besides one furnace at Domnarfvet, Sweden, for the production of 2500 tons of pig-iron per annum, with one in Norway and one at Trollhättan, Sweden, both in course of construction, and each designed to produce about 7500 tons of pig-iron annually. Of the Héroult furnaces, the total capacity per charge of those working was about 80 tons, and of those in course of construction about 50 tons. The Girod furnaces, the great competitors of the Héroult, were recorded at about 38 tons in work and 26 tons being built. Similarly, the figures for the Keller were 13 tons and 5 tons, and for the others 20 tons and 13 tons respectively.

Of the induction furnaces, the Kjellin furnaces erected totalled fourteen, with 35 tons capacity; the Röchling-Rodenhauser fifteen, with 30 tons in work, 1 ton not in work, and 17 tons capacity being built; all others about 18 tons in work. That gave a total capacity of about 250 tons for the arc furnaces and 100 tons for the induction, or a grand total of 350 tons per charge for all electric steel-melting furnaces. Pressure of other work has prevented me from getting the latest figures from all the firms making electric furnaces, but I have obtained these from the two most important firms, viz. the Héroult and the Kjellin and Röchling-Rodenhauser, and in this connection would record my best thanks to Mr. Donald F. Campbell and Mr. E. C. Ibbotson, respectively, for their kind help and trouble in getting me this information. Comparing the Héroult furnaces only, as an example, we have seen that in June, 1910, there were twenty-nine of these furnaces with a capacity of 80 tons in work and 50 tons in course of erection, 130 tons in all; whilst about June, 1911, there were forty-three furnaces, with a total capacity of about 242 tons

The output of electric steel in Germany, the United States, and Austria-Hungary in 1910 amounted to almost 112,000 tons, which is an increase of 63,000 tons over the figures for 1909. These are the only countries for which the exact output of electric steel is published, but there is no doubt that the figures for Sweden, France, Belgium, and Italy would also show large gains. The increase will probably be more than maintained in 1911, as more than thirty new furnaces of various types should be started during the year, and many which only started towards the end of 1910 will put in a full year's work in 1911. England will also for the first time appear as a regular producer. Before the beginning of the present year the Héroult furnace at Edgar Allen's in Sheffield was the only arc one in steady operation. In January three Héroult furnaces were commenced in England: at Vickers' and Thos. Firth and Sons' in Sheffield, and at Lake and Elliott's in Braintree, Essex. A Grönwall furnace, for demonstration and manufacturing purposes, also started at about the same time in Sheffield; and the output of England for 1911 should amount to about 13,000 tons. A 15-ton Héroult furnace is to be erected at Skinningrove shortly, and is expected to turn out 200 tons per day. About the same period Kjellin induction furnaces have been working satisfactorily at Vickers and Jessop's in Sheffield and an experimental furnace at the University of Sheffield.

Great progress will be made in Germany with electric furnaces during the next year, when Héroult furnaces of 25 and 22 tons capacity are to be constructed. At present the largest size are the two 15-ton Héroult furnaces at S. Chicago and Worcester, belonging to the United States Steel Corporation, who have recently acquired the Héroult patents for America, and will probably erect several more furnaces shortly.

The electric furnace can be used either for melting scrap directly or in combination with some other form of furnace, in which case it simply acts as a refiner. The majority of the recent furnaces have been employed in this way, in conjunction either with Bessemer or open-hearth furnaces. The latter are usually of the basic tilting type, part of the charge being removed to the electric furnace after the pig is melted and the bulk of the phosphorus removed, leaving some phosphorus and the oxygen and sulphur to be eliminated by the electric furnace. In this case the time required for the electric furnace is from one hour to two hours, according to the degree of refining required and the original condition of the steel when removed from the basic furnace. The power used varies from 100 to 300 kw. hours per ton. When cold scrap is melted the time required is about six hours, and the power consumption said to be from 650 to 750 kw. hours; but really, all in, more probably 800 to 1000 per ton. Of the forty-four Héroult furnaces in operation or construction twenty-one are to melt scrap, twenty to take molten steel from the basic open-hearth, one from a Talbot furnace, and two from converters.

Electric furnaces are being employed in the following cases:—

(1) To replace crucibles. The gain is then one of cost of production.

(2) For foundries. Electric furnaces are being used in many foundries. At Georg Fischer's and Schaffhausen they are the only furnaces employed, and Lake and Elliott, of Braintree, are now making most of their steel electrically.

(3) To replace Swedish Bessemer steel, and for steel of axle and tyre quality.

(4) For weldless tubes. The Mannesmann Company has Héroult furnaces in Germany and Italy.

(5) In combination with Talbot furnaces. Owing to the fact that the heat need not be sufficiently great for teeming on transference to the electric furnace, the output of the Talbot and the life of the lining and roof are said

to be largely increased. This will be the procedure at Skinningrove for making rails.

(6) For melting turnings, especially high-speed turnings. These make excellent scrap for the electric furnace. Nickel scrap can be melted without any loss of nickel.

There are two aspects of the present position of a comparatively new industry. One is the progress made during the year, and an endeavour has been made to present that point of view. Another aspect is the actual state of the industry at present, and that can best be judged by the following two tables representing the furnaces, capacities, and kind of work done by all the furnaces under the care of the two principal firms already named. A very interesting item in the induction-furnace list is the entry representing the fact that the Kjellin furnace has been adopted for melting the metal for the manufacture of those delightful, though expensive, culinary vessels of pure nickel so much appreciated now.

Besides: 1 Furnace at the Berndorfer Metallwarenfabrik, A. Krupp, Berndorf, for treatment of nickel and nickel alloys.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Recent appointments include:—Mr. J. E. Coates, special lecturer in physical chemistry, to succeed Prof. Alex. Findlay; Dr. E. P. Frankland, Mr. P. May, and Mr. Ernest Vanstone assistant lecturers and demonstrators in chemistry; Dr. Thomas Yates, special lecturer in osteology; Dr. J. R. Heath, lecturer in physiology.

The council of the University has decided to increase from 25*l.* to 100*l.* the annual grant to the Workers' Educational Association, which provides classes for working men and women.

PROF. G. E. HALE is prepared to receive applications for the post of assistant in the department of stellar spectroscopy at the Mount Wilson Solar Observatory. Practical experience of observatory work is desirable, and a knowledge of physical optics and spectroscopy is essential.

THE *London University Gazette* announces that a bequest has been made to "the governors for the time being of University College" by the late Mr. A. R. T. Momber of certain shares of his estate. Under the benefaction a sum of 7000*l.* will eventually accrue to the University.

IT is stated in *Science* that President W. H. P. Faunce has announced that 80,000*l.* of the endowment fund of 200,000*l.* which Brown University is endeavouring to secure has already been subscribed. The General Education Board has contributed 30,000*l.*, and eight gifts of 5000*l.*, together with smaller amounts aggregating 10,000*l.*, have been received. From the same source we find that Mr. Charles Scribner has given to Princeton University a completely equipped printing plant, provided at a cost of 25,000*l.*

AN appeal for funds towards the establishment of a modern university in Central China at Hankau-Wuchang has just been made. The scheme is promoted by committees representative of the Universities of Oxford, Cambridge, and London in this country, and of the Universities of Harvard, Columbia, California, and Toronto in Canada and the United States of America. During the three years which have elapsed since its inception the committee has been engaged in settling the lines upon which the University is to be founded, in locating the most advantageous site, in appointing the first president (Mr. W. E. Soothill, late principal of the Imperial University of Shansi), and in other essential preliminaries. An appeal is made for a capital sum of 250,000*l.* for the foundation of the University, the purchase of a site, the erection and equipment of buildings, and the endowment of professorships. It is hoped that one half of this sum, 125,000*l.*, will be the British contribution towards the project, and that the other half will be contributed by America. The general basis of the University will be that of a teaching and examining body working in cooperation with a number of self-governing residential colleges and hostels. The foundation of a university for Central China is desirable on the ground that in this way Great Britain and America can render to China at the present stage a service of incalculable importance and of far-reaching consequence. A seat of learning will thus be established in China which will be inspired by the best traditions of the cooperating Western universities. Donations can be sent to the Most Hon. the Marquess of Salisbury, G.C.V.O., 20 Arlington Street, London, W., or to the honorary treasurer, University for China, 22 Albemarle Street, London, W. Cheques should be drawn in favour of the "University for China." Further particulars can be obtained from the secretary, 22 Albemarle Street, London, W.

THE Education Committee of the London County Council at a recent meeting came to certain important conclusions as to applications from the Senate of the University of London for maintenance grants in aid of incorporated schools and institutions maintained by the University. After reviewing the conditions in the various colleges, the following resolutions were eventually adopted:—"That the Senate of the University of London be invited to prepare and submit to the Council a statement of the policy which it intends to pursue pending the publication of the report of the Royal Commission on University Education in London, together with an estimate of the additional assistance (if any) which may be required from the Council to enable such policy to be carried out." "That, on receipt of the statement and estimate referred to in the foregoing resolution, the Council will be prepared to consider as to the amount of assistance it should give to the University during the academic years 1911–12, 1912–13, and 1913–14; and that the Senate be so informed." "That the Council is not prepared, during the period of three years referred to in the foregoing resolution, to consider any applications for further maintenance grants either for the educational work conducted directly by the University or for the maintenance of the incorporated schools; that the Council does not undertake to continue, after the expiration of the above period of three years, any grant which it may decide to make to the University under the above-mentioned recommendations; and that the Senate be so informed." The committee thinks it is of great importance that it should be clearly laid down that any grant which may be given will be strictly temporary. On the publication of the report of the Royal Commission the whole question of the future government and policy of the University will have to be dealt with, and, among other important questions, that of the relation of the University to the schools which are at present incorporated will come up for discussion. The London County Council, as the authority for higher education in London, should be able, the committee maintains, to impress its views upon these matters upon Parliament and the governing body of the University. The most effective way in which the Council can impress its views is by means of its maintenance grants, and the committee thinks that it must be made clear that the Council will be in no way pledged to continue any grant which it may decide to make to the University at the present time.

THE annual meeting of the Association of Teachers in Technical Institutions was held on November 4. In moving the adoption of the report of the council, Mr. North, the president, directed attention to the evidence which had been given by the association to the Royal Commission on the London University, emphasising the necessity for the formation of an autonomous faculty of technology within the University, and urging that the Imperial College of Science, the London polytechnics, and possibly some provincial technical institutions should form constituent elements of this faculty. In discussing the recent Board of Education circular relating to the new scheme of examinations and grouped courses, he regretted the hasty manner in which the scheme of the Board had been brought into operation. The circular showed a lack of practical knowledge of the actual conditions of the work in technical institutions comparable with that displayed by the Board in the changes introduced last year in the matter of registration. Mr. North referred also to the steps which had been taken by the council in the direction of securing the presence of teachers from technical institutions upon all local advisory committees dealing with juvenile employment. In seconding the adoption of the report, Mr. Abbott, the honorary secretary, pointed out the necessity for the association to continue its efforts for the development of technical education. At the present time technical education in England, if not actually on the down-grade, is stationary. The returns recently published by the Board of Education for the session 1909–10 show that the number of day students in technical institutions is slightly lower than that in the previous session, while the number of evening students is practically the same. After the adoption of the report a discussion was opened by Prof. Schwartz upon the changes recently made by the Board of Education with regard to the abolition of all first-stage examinations and the withdrawal of all examinations in certain subjects. He welcomed this change as one which would lessen the weight of external examinations, which have, up to the present, lessened the real educational work of the technical institutions. He advocated the replacement of the external examinations in Stage i. by internal examinations in the case of the larger institutions, and possibly by groups of institutions for the smaller schools. The president of the association for the year 1911–12 is Dr. J. Clark, rector of the Kilmarnock Academy, and director of technical education for Kilmarnock.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 2.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir W. de W. **Abney**: Colour-blindness and the trichromatic theory of colour-vision. Part iii.—Incomplete colour-blindness. The first part of the paper shows how, if an equation be formed by rays in known position in the spectrum to match a white, by normal vision and by the colour-blind, the two can be compared together without special reference to the luminosity of the matched white. The luminosities of all the rays are known in the one case, and only two in the second, and from the two matches the unknown deficiency of colour sensation can be calculated. Owing to the fact that large quantities of their white can be mixed with the colours without being detected by those incompletely colour-blind who have a small factor for one of their sensations, a very false interpretation of their colour-blindness might be arrived at by the method described above. If, however, the luminosity of the composite white and the matched white be carefully equalised, a full determination of the colour deficiency can be arrived at by treating the equation somewhat in the manner described in part ii. of this same subject, when a true result is obtained. The latter part of the paper dealt with colour equations made from the rotation of discs; and it is shown that trustworthy results can be obtained from their use so long as the sensations stimulated by the pigments in the light in which they are viewed are known in amount. The method of ascertaining the sensation composition of the pigments, and of the light used for their illumination, is described. When once these are known, no further appeal to the spectrum is required. The author recommends the use of a white light passing through a yellow substance, such as chromate of potash solution, as a viewing light, in which only the red and green pigments are required in the inner disc, the blue not being wanted. The "grey" match becomes thus much brighter and is easier to read.—H. R. A. **Mallock**: Note on the iridescent colours of birds and insects. In this note reasons are given for the view that certain forms of brilliant coloration which occur in the feathers of birds and in the scales and integuments of insects are due to interference, and are of the nature of the colours of thin plates. Walter, in 1895, in Germany, and quite recently Michelson in America, have written on this subject, and, basing their opinions on the behaviour of polarised light when reflected from the colour-producing surfaces, conclude that the colours are due to selective absorption and reflection, and are akin to those reflected from certain anilin dyes and from metals. The reasons against this view and in favour of interference are (1) that when any of these natural colour-producing structures are penetrated by a fluid having the same refractive index as that of the material of which the structure is composed, the colour disappears; (2) when the refractive index of the fluid is less, the colour does not disappear altogether, but changes towards the red; (3) (which is perhaps the most important) under mechanical pressure the colours first change towards the red and then (as the pressure increases) disappear. These results are what might be expected from a structure which produces interference, and it is difficult to reconcile them with any other hypothesis. The note is founded on observations, extending over many years, on examples of this class of colour production taken from a considerable number of orders and genera, both of birds and insects, and the methods of examination employed are shortly described.—K. R. **Lewin**: The behaviour of the infusorian micronucleus in regeneration. When *Stylonychia mytilus* is cut in two, so that each merozoon receives one member of the meganucleus and one micronucleus, both fragments exhibit in favourable circumstances complete regeneration. This involves segmentation of the meganuclear member and division of the micronucleus. If a portion of the cytoplasm be removed from the hind end of the animal without disturbing the nuclei, there may occur during regeneration a division of one, usually the posterior, micronucleus. The result is to furnish the regenerated infusorian with three micronuclei instead of two, *i.e.* the division does not restore, but actually disturbs, the nuclear relations characteristic of the race. When the regenerated individual proceeds to fission, all three micronuclei divide. That an extra division can be introduced into the normal cycle of mitoses shows that the organella is in a fit state to divide before the whole animal is ready for spontaneous fission; that the supernumerary mitosis occurs during regeneration suggests that the stimulus causing the micronucleus to divide may be the condition of the surrounding cytoplasm which obtains during the constructive activities of regeneration. The cases in which regeneration occurs without either of the micronuclei dividing can be supposed to be those in which either the micronuclei were not ripe for mitosis or the stimulus was not sufficiently intense to evoke a division—by reason, *e.g.*, of regeneration occurring slowly, with no great intensity of constructive processes at any time. At the normal fission of the animal, when all the micronuclei present divide, there is a general formation of new parts quite comparable with the localised activity in regeneration, and accomplished, it is natural to suppose, with much the same condition of the cytoplasm. The normally occurring mitoses, and those taking place during regeneration, can thus be brought under one point of view.—A. F. **Hayden** and W. P. **Morgan**: An inquiry into the influence of the constituents of a bacterial emulsion on the opsonic index. These experiments, so far as they have gone, show that in the technique of the estimation of the tubercle opsonic index the quantity and character of the contents of the bacterial emulsion must be taken into account, and that the chief factor influencing the estimation is the finely ground bacterial detritus resulting from the process of triturating the dried culture of the bacillus.—Colonel Sir David **Bruce**: The morphology of *Trypanosoma gambiense* (Dutton).—A. H. **Caulfeild**: (1) Factors in the interpretation of the inhibitive and fixation serum reactions in pulmonary tuberculosis; (2) preliminary report upon the injection of rabbits with protein-free (tuberculo-) antigen and antigen-serum mixtures.

Physical Society, October 27.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Hon. R. J. **Strutt**: Further observations on the afterglow of electric discharge and kindred phenomena. It is shown that ozone prepared by means of the Siemens ozone tube used at atmospheric pressure is able, when mixed with nitric oxide, to give the greenish-yellow afterglow flame. This result is only attained, however, when the ozone has been concentrated by fractional distillation. A blue glow is obtained under the same conditions with sulphuretted hydrogen and ozone. The effect of sulphur compounds in improving the air-glow noticed by the older experimenters is shown to be due, not to any direct intervention of these bodies in the reaction, but to their power of destroying organic matter prejudicial to ozone. When once this is got rid of, the sulphur compounds are of no further advantage. It is found that pure oxygen does not give an afterglow. The afterglow seen in electrodeless bulbs containing oxygen is due to some interaction with water vapour. The luminosity given out when ordinary spring water is shaken with ozone is shown to be due to oxidation of peaty matter contained in it. Brown peat water gives greatly enhanced luminosity.—Prof. C. G. **Barkla** and J. **Nicol**: Homogeneous fluorescent X-radiation of a second series. It was shown by one of the writers that the fluorescent X-radiations emitted by elements exposed to primary Röntgen radiation can be arranged in series, one radiation in a particular series being emitted by each element, and the radiation belonging to that series becoming more penetrating with an increase in the atomic weight of the radiating element (Proc. Camb. Phil. Soc., May, 1909). The homogeneity of radiations of only one series (the K series) was shown by Barkla and Sadler. This paper describes experiments showing the homogeneity of fluorescent X-radiations in the second series (the L series), and exhibiting the homogeneity of radiations of the two series from a number of elements. Details are given of the observations on the radiations from barium. Similar results are recorded in the case of the radiations from iodine, antimony, and silver. The homogeneous fluorescent radiations of different series are emitted simultaneously by an element exposed to Röntgen radiation of more penetrating type than either. The fluorescent X-radiations can

thus be analysed into well-defined radiations widely different in penetrating power, and may be said to give a line spectrum in X-rays. The absorbability of the fluorescent radiations is given by the following values of λ/ρ, where λ is the coefficient of absorption of these radiations in aluminium of density ρ:—

Ag radiation:	(Series K)	[2·5];	(Series L)	700

Ba	,,	0·8	,,	224

Paris.

Academy of Sciences, October 30.—M. Armand Gautier in the chair.—B. **Baillaud**: Presentation of two volumes of the "Annales de l'Observatoire de Paris."—Ch. **André**: The formation of suns. Referring to recent adverse criticisms of Laplace's theory, the author maintains that recent physical researches confirm this theory.—A. **Demoulin**: The R surfaces.—Eugenio Elia **Levi**: Periodic differential equations.—Paul **Dienes**: The summation of Taylor's series.—Henry **Hubert**: The parabolic form of the exposed acid crystalline rocks in western Africa. The water erosion takes place only at the expense of granitic rocks, and is characteristic of certain regions. The effect of the motion of the cutting particles is shown to result in a curved outline.—G. **Millochau**: Contribution to the study of the spectral effects of electric discharges in gases and vapours. The image from a vacuum tube containing the gas under examination at a known pressure is projected on to a circular photographic film rotating at a high known velocity. Seven kinds of simple discharge are described, and three types of mixed discharge. All the results are in accord with hypotheses which connect the production of the spectrum with the temperature of the molecule and the dissociation effects corresponding with that temperature.—Albert **Colson**: The theory of solutions and heats of solution. The author regards the identification of the dissolved particle with the chemical molecule as inadmissible, and considers that the dissolved particle is generally polymolecular. He suggests *dissolecule* as a distinctive name for the dissolved particle. The difference between the heat of solution of a gas and its heat of condensation, which should be zero according to the van 't Hoff hypothesis, represents the heat disengaged by the molecular contraction giving rise to the dissolecule.—MM. **Broniewski** and **Hackspill**: The electrical properties of the alkali metals, of rhodium, and of iridium. Measurements are given of the thermoelectric power of cæsium, rubidium, potassium and sodium, and of rhodium and iridium. The purification of the alkali metals was effected by distillation in a vacuum.—G. D. **Hinrichs**: The atomic weights of the dominant elements.—E. **Chablay**: The use of liquid ammonia in chemical reactions. Researches on the alcoholates. An alcohol dissolved in liquid ammonia immediately decolorises a blue solution of potassammonium or sodammonium, hydrogen, ammonia, and the anhydrous alcoholate RONa being formed. A blue solution of calcium-ammonium reacts similarly, the calcium alcoholate being formed. Barium and strontium ammoniums act similarly.—Maurice **Lanfry**: The oxy-β-methylthiophenes.—MM. **Taffanel** and **Dautriche**: The mode of firing explosives. In blasting in mines one cartridge containing fulminate is usually arranged to explode several cartridges containing safety explosive only. Experiments are described showing the most advantageous arrangement of the fulminating cartridge with respect to the others.—Jean **Friedel**: The effect on vegetation of a more complete darkness than that currently employed in laboratories. A box for growing plants in the dark is described in which the exclusion of light is so perfect that a delicate photographic paper is unaffected after prolonged exposure. The results on the plants are compared with those obtaining under ordinary conditions, in which the exclusion of light is not so perfect.—Pierre **Berthault**: The variations of tuberiferous Solanum.—P. **Desroche**: The action of various light radiations on the motion of the zoospores of Chlamydomonas.—A. **Marie** and A. **Bonnadieu**: Leucogenesis and intestinal epithelium.—A. **Magnan**: Human monsters.—Pierre **Georgevitch**: The formation and germination of the spores of *Bacillus thermophilus vragnensis*.—Louis **Gentil**: The country of Zaër, western Morocco.—Maurice **Lugeon**: The existence of two phases of Palæozoic foldings in the western Alps.—Carl **Renz**: The extension of the Palæozoic formations in the islands off the coast of Argos.—Fernand **Meunier**: The Blattidæ of the Commentry Coal-measures. The lake of Commentry would appear to have been inhabited by a fauna of Blattidæ, less rich than in the American deposits, and represented by a very small number of genera, some of which possessed extremely prolific species.—Ch. **Moureu** and A. **Lepape**: The rare gases in fire-damp. Analyses of five specimens of fire-damp collected under conditions excluding air. One striking fact brought out by these analyses is the much higher proportion of helium to nitrogen than that existing in air. The nitrogen from the Mons specimen contained no less than 13 per cent. of helium.

CELLULOSE DERIVATIVES IN THE SERVICE OF MAN.

Nitrocellulose Industry: a Compendium of the History, Chemistry, Manufacture, Commercial Application, and Analysis of Nitrates, Acetates, and Xanthates of Cellulose as Applied to the Peaceful Arts; with a Chapter on Gun-Cotton, Smokeless Powder, and Explosive Cellulose Nitrates. By Dr. Edward C. Worden. Vol i., pp. xxxiv+565. Vol. ii., pp. xxviii+567–1239. (London: Constable and Co., Ltd., 1911.) Price, two vols., 42s. net.

WHEN Schönbein first announced his discovery of gun-cotton little could he have foreseen that he was laying the foundation of so many important industries as those, sixty-five years later, associated with cellulose derivatives, for although the acetates and xanthates of this parent substance are daily growing in importance, their introduction has solely been due to the wide and successful application of the nitrocelluloses. One may safely say that the derivatives of no other single chemical substance (if cellulose in its varied forms may be so termed) have proved of such general use to mankind, assisting in the production at a cheap rate of numbers of articles hitherto made from expensive natural products, developing important branches of photography, rendering valuable service to the man of science and medical man, and finally furnishing the base of all the modern smokeless powders. The author has succeeded in these two comprehensive volumes in admirably treating of all the discoveries and applications of these highly important derivatives. The magnitude of such a work and the thoroughness with which it has been carried out may be realised from the fact that more than 8000 literature references and 5000 patent references have been verified.

The preparation of the nitrocelluloses and their stabilising is of the first importance, and is very clearly dealt with. An important point is the effect of prior treatment of the cotton, before nitration, on the character of the product and its stability. In general cotton treated with bleaching powder solutions or mercerised by alkali gives a lower nitrogen content, a greater ether-alcohol solubility, and renders subsequent stabilisation more difficult.

The successful application of nitrocelluloses in the arts is almost wholly dependent on the use of proper solvents and obtaining solutions of the desired viscosity. The important part which amyl alcohol (*iso*), introduced by Stevens in 1882, has played in the artificial leather, lacquer, and other industries is paralleled by the important property of camphor in forming solid or suitable plastic bodies for other branches of the industry. The author estimates that some 450,000 gallons of amyl acetate are annually employed in the United States, so that he rightly devotes considerable space to its preparation and the chemistry of camphor also receives very full treatment.

Space does not permit of more than a brief reference to the numerous applications of nitrocellulose or the other derivatives; it seems that in one way or another they must have some interest for everyone, but especially for those engaged in any branch of science. The preparation of museum specimens, and particularly of sections for the microscope; for preservation of important writings by saturation of the paper (where Indian ink has been employed, of which shellac is a constituent and soluble in the nitrocellulose solvent—the paper must first be immersed in a 2 per cent. solution of gelatin and allowed to dry); for the production of special tubes for deep-sea soundings, the tubes being coated inside with silver chromate, are amongst the minor but still important applications of nitrocellulose solutions.

In the large industries built up on cellulose derivatives during the last twenty years mention may be made of its application in the manufacture of incandescent mantles, both for coating the mantle to enable it to withstand the shocks of transport and handling, and the production of mantles themselves by the ejection of filaments containing the thoria and ceria, to be afterwards woven into mantles; the production of pyroxylin containing imitation leathers, of which a conservative estimate of the daily output of the United States is 45,000 yards, and for photographic purposes, where the applications of soluble nitrocelluloses are so numerous that considerable space is devoted to the subject. The production of continuous films has undoubtedly contributed more than any other discovery to the popularity of photography, and rendered the kinematograph a possibility. The extreme desirability of using non-inflammable films is emphasised from time to time by the ignition of ordinary films, so that the description of the preparation of cellulose acetate films will prove of value and a useful guide to future inventors.

The production of artificial silk is a triumph of the application of chemical substances to rival one of the most beautiful products of nature. Whilst in the early days it was thought to be a rival to the natural product, its lack of flexibility and strength have precluded this actually being the case; but the beauty of the filaments has given rise to so many new and decorative materials that, although not a rival, the demand for the artificial product was, for a period, so great that its price actually exceeded that of the natural silk. A brief reference can only be made to the early process of Chardonnet (1884), in which, as in most processes, an ether-alcohol solution of nitrocellulose is employed. The fluid was at first squirted through an orifice 0·5 mm. in diameter, the spinnarets falling into cold water which coagulated, their exterior forming a tube with a liquid interior, this coarse thread being then rapidly spun out into a thin filament. Later the orifice was reduced to 0·08 mm. Nitrocellulose silks are usually denitrated by means of an alkaline sulphide, so that finally they are essentially cellulose. It is of interest to compare the diameter of the artificial fibre with the natural. Chardonnet silk is given as 45 to 60 micromillimetres, while the natural silk is only 9 to 15, these figures being for the wet (swollen) fibres.

D

The chapter on the military applications of cellulose derivatives is limited to eighty-five pages, but these contain a vast amount of information which, although familiar to those associated with this branch of the subject, is an excellent condensation of information.

So wide are the applications of cellulose derivatives and so admirably is the subject treated by the author that his two volumes should find a place in every technical and scientific chemist's library, and, further, will prove an invaluable reference book for the large number who are regularly employing many of these important bodies in their everyday work.

J. S. S. B.

EDUCATION FOR THE COUNTRY LIFE.

The Teaching of Agriculture in the High School. By Garland A. Bricker. Pp. xxv+202. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 4*s*. 6*d*. net.

STUDENTS of rural affairs have long realised that much dissatisfaction exists in country districts with our present system of education. In whatever way it is judged, according to its critics, it has failed; the children sent out from the country schools are not better fitted for work on the land than their fathers were; on the contrary, they are kept at desk work during the period when it is supposed that their receptive faculties are at the best, and when they would, on the land, most rapidly learn the ways of animals, of plants, and of soils. Even the friends of the system will concede that it has been evolved without any special regard for country requirements, and without taking account of the fundamental differences in habits of thought and in points of view between the dwellers in the town and those in the country.

More and more it is being realised that the future development of the rural district, or to put it still more widely, of the country civilisation, must run on different lines from that of the city, and experiments are therefore being made to evolve a system of education that shall train children to lead the life of the country. The experimental scale is largest in the States, as one might expect, and in the book before us Mr. Bricker has collected such of the material as is at present available, thus usefully filling a gap in our education literature. It is, of course, as yet too soon to speak about results, but during the experimental period it is useful for educationists to know what their American *confrères* are doing.

Of the elementary school but little is said. The nature-study idea is for the present the best we have, and has already a copious literature of its own. The work of the elementary schools, according to the author, should confine itself to an elementary study of the common things of the farm, field, and forest. Something of the relative importance of these things to man should be studied and fixed in the mind of the child before he leaves school. It is in the secondary school, or, as it is here called, the high school, that the scholars will take up agriculture as such, but there is no break in the sequence of studies because agriculture will be looked upon as nature-study *plus* utility. But the study of agriculture is to be an education and not simply a manual training:

"If the essence of true culture is to see the fundamental and eternal shining out through the seemingly trivial and transitory, there is no subject better adapted to provide culture than the subject of agriculture."

To be treated in this broad way, agriculture requires a larger place in the school curriculum than the established secondary schools are able or willing to give it; hence the necessity for separate agricultural schools. Two possible dangers are indicated: specialised schools may emphasise class distinctions unworthy of a democratic country; education that makes a strong appeal to economic motives may be harmful if it places its powerful sanction on self-seeking ideals. The purely practical man, of course, will ask: Of what use are culture and adornment if the power to earn a livelihood is lacking? But this must not be the point of view of the agricultural teacher. He must rather insist on the other question: Of what use is the best capacity to make a living without a corresponding power to make life worth while? and make agriculture a cultural as well as a vocational subject. In short, the agricultural secondary school is to be the directive and constructive agent of the new rural civilisation that the best men in the States (and, for that matter, in this country also) are endeavouring to foster.

A chapter is devoted to the description of schools already established. They are, as one would expect, of several types, but in all of them boys and girls are educated together, entering at the age of thirteen or fourteen, and remaining for three or four years. Agriculture for the boys and household science for the girls form the respective centres of the courses, and the education is made as real as possible, *i.e.* the thing itself, whether a horse, a maize seed, or a growing crop, is before the class, and not simply a picture.

The author then proceeds to a discussion of methods. The logical arrangement of subjects followed in a college course is not the best for the boy with his limited experience and his incomplete and unorganised knowledge. It is necessary to adopt a psychological arrangement, *i.e.* a sequence of studies adapted to the changing and developing powers of the scholar. That the subject generally accords with the instincts and the impulses of the average boy is a tremendous help, and yet, unintelligently directed by the teacher, this help may prove a great danger. Into the psychological discussions we need not enter. The author's aim is to show that pedagogic principles can and should be applied to the teaching of agriculture, and that the subject can and should be made cultural as well as vocational.

The book affords a striking illustration of how much further the Americans have got than we ourselves. We are only commencing—if indeed we have seriously commenced—to apply the science of education in our agricultural teaching. Those who propose to essay the task will obtain useful help from this book.

E. J. R.

GLACIERS AND ICE-SHEETS.

Characteristics of Existing Glaciers. By Prof. W. H. Hobbs. Pp. xxv+301. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 13*s*. 6*d*. net.

THE framework of this volume was laid by Prof. Hobbs in three papers, dealing in turn with "Mountain Glaciation," "The Ice of Arctic Regions," and "Antarctic Ice," which were published during 1910 in scientific journals respectively in London, Philadelphia, and Berlin. The author has done good service to the glaciologist and glacial geologist in bringing together his concise description and classification of existing glaciers and ice-sheets in the present convenient form. Especially in the parts devoted to Arctic and Antarctic ice he has made an exhaustive digest of the scattered literature, and has presented a copiously illustrated summary of the available information respecting the distribution and character of the ice of these regions. To the end of each chapter he appends a full list of his authorities, so that the book is in every respect a most useful work of reference. His outlook is throughout that of a physiographer of the modern American school, and he has constantly in view the effect of ice and snow upon the shape of the land beneath it.

In his treatment of mountain glaciers, in the first (and shortest) part of his book, the author asserts himself more prominently than in the later parts, and it may be that some of his readers will consider the value of this part as a digest has, in consequence, been impaired. He reduces the existing Alpine glaciers to their really insignificant position by the aid of comparative diagrams (*e.g.* plate ii.). He will not allow that any of them, with the possible exception of the Great Aletsch, are worthy even of being called valley-glaciers—"In reality the glaciers of the Alps, far from occupying valleys, do not even fill the mother cirques at the valley heads" (p. 52). His rather elaborate classification of mountain glaciers (p. 42), based partly upon comparative alimentation, is not, however, likely to be generally adopted; most of the "types" are necessarily nothing more than phases which merge together indefinitely both in space and time-relation.

With respect to the long controversy as to the potency of ice as an eroding agent, Prof. Hobbs in his preface explicitly disclaims any intention to deal with "the views of that school of British geologists particularly which holds that the denudational effect of glacier ice is negative." So he does not refer to these views in adopting alternative explanations of the critical phenomena; *e.g.* the "Cascade Stairway" and the "Hanging Valley," in chapter iv. In this connection it may be remarked, though not mentioned by the author, that the long trench-like valleys by which the great glaciers pour down to the ice-plain of the Barrier from the high Antarctic plateau can scarcely be assigned to any other cause than ice-erosion.

In discussing the relation of mountain-form to glaciation, Prof. Hobbs dwells with particular emphasis upon cirque-development, which he believes to have a greater importance than has been generally recognised; and in this branch he takes upon himself the *rôle* of special pleader. For the initiation of a cirque through the agency of a snow-bank, he calls in the process of "nivation," *i.e.* selective perishing of contiguous moistened rock, as first suggested by Mr. F. E. Matthes from his observations in the Bighorn Mountains of Wyoming. In the later development of the cirque, the berg-schrund is considered to be a prime factor by the author, who has been duly—possibly even unduly—impressed by results of Mr. W. D. Johnson's celebrated exploration of the berg-schrund of Mount Lyell glacier, California, where the sapping of a perpendicular wall of rock was found to be in progress at the bottom of the fissure. The basis of observation is so limited that it may legitimately be questioned whether this sapping effect is general. However, the author considers that cirque recession is mainly responsible for the residual topographical forms of most high mountains, and he illustrates the progressive stages by good examples from western U.S.A., stating that "in parts of Europe, and in the Alps in particular, one looks in vain for evidences of the earlier and more significant stages," owing to the more prolonged and vigorous glaciation.

In final chapters the meteorological conditions of existing ice-sheets are summarised, and it is considered that the strong radial winds of Greenland and the Antarctic are due to the sliding outward of chilled air along the surface of the ice-dome.

The author fully recognises in other parts of his work the proved aridity of both polar areas, but passages on pp. 42–3 and 100–1 are likely to give the erroneous impression that the ice-caps are areas of heavy precipitation. At p. 238 there is an obvious misprint of Arctic for Antarctic.

Independently of the author's opinions on debatable matters, which may or may not be acceptable, every geographer and geologist interested in ice will appreciate these clear descriptions and excellent illustrations of the earth's great glaciers—they make up into a most presentable book.

G. W. L.

PRECESSION AND PARADOX.

Draysonia: being an Attempt to Explain and Popularise the System of the Second Rotation of the Earth, as Discovered by the late Major-General A. W. Drayson; also giving the Probable Date and Duration of the Last Glacial Period, and Furnishing General Drayson's Data, from which any Person of Ordinary Mathematical Ability is Enabled to Calculate the Obliquity of the Ecliptic, the Precession of the Equinoxes, and the Right Ascension and Declination of the Fixed Stars for any Year, Past, Present, or Future. By Admiral Sir A. F. R. de Horsey, K.C.B. Pp. ix+76+diagram. (London: Longmans, Green, and Co., 1911.) Price 3*s*. 6*d*. net.

GENERAL DRAYSON'S book on the "Motion of the Fixed Stars" is not a model of lucidity and generally fails to convince those who endeavour to grasp its argument. It was, therefore, most desir-

able that in selecting a commentator and literary executor the choice should fall on one who possessed the power of removing what was obscure in the theory and of placing the scheme in the most advantageous light. Admiral de Horsey has nothing to recommend him for the office he has undertaken but an unstinted admiration for the original author and a loyal desire to secure his recognition as a profound thinker. We respect and admire the sincerity of his conviction and his resolute effort to uphold the reputation of his departed friend. The struggle he has made is pathetic, but we regret to say he has only succeeded in darkening the issue.

General Drayson was dissatisfied with the theory of precession. He could not accept the explanation of the change of coordinates as due to the revolution of the earth's pole about that of the ecliptic, while at the same time the obliquity of the ecliptic was continually varying. He did not admit that the circular motion was a close approximation to the truth, and that greater accuracy was obtained by making the radius of the circle vary. Yet the device is a very usual one in the explanation of a recondite subject. It is often found that a broad general truth requires a minute degree of qualification. "The geometrical absurdity of a circle with a movable centre" seems to have presented a difficulty that the gallant General never mastered, and he therefore devised another plan for computing precession. Owing to the slow motion of the earth's pole, there is no difficulty in contriving an arithmetical process, by which the results when confined to a limited number of years shall be similar to those obtained by the ordinary formula. General Drayson's plan was to make the earth's axis revolve in a circle of radius 29° 25′ 47″, about a point 6° from the pole of the ecliptic, and situated near the solstitial colure. The annual motion of the point marking the origin of longitude (apparently not precisely coincident with the first point of Aries) is 40·89″, consequently the cycle of precession is about one-quarter longer than that assigned by astronomers.

Admiral de Horsey's contribution in support of his friend's theory has been to compute the precession of many stars by this method, and to compare the results with the Nautical Almanac values. The agreement is satisfactory, but if this proved anything one would think it proved the Nautical Almanac correct; but that view does not commend itself to the Admiral. Partly perhaps because in Drayson's method the obliquity of the ecliptic will vary in the course of a cycle between 23° and 35°, and thereby the glacial theory, provided that geologists could be satisfied with so short a period as 15,000 years, might be satisfactorily accounted for. The author also claims that some difficulties he imagines to exist in the reckoning of time can be removed by this means of explaining precession. He is not, however, very fortunate when he puts the late Mr. Stone in the witness-box to prove an anomaly in time reckoning. This may be a small matter, but when the author confuses precession with aberration we feel that, with the best intentions of serving the interests of his lost friend, he is scarcely fitted for the task.

THE MEASUREMENT OF ILLUMINATION.

Illumination; its Distribution and Measurement. By A. P. Trotter. Pp. xvii+292. (London: Macmillan and Co., Ltd., 1911.) Price 8*s*. 6*d*. net.

DEDICATED to Pierre Bouguer, the father of photometry, this book is the first really scientific attempt to put illuminating engineering on a proper basis, and is the outcome of the work which has been done in America and England of late years to break away from the haphazard methods of lighting which have so long been in vogue, and to replace them by arrangements of the sources of light which shall lead to a satisfactory distribution of light over the area to be illuminated.

No one more fitted to undertake this work than Mr. A. P. Trotter could have been found, and the experience he has gained since 1879, when he worked out his dioptric system of uniform distribution of light, has enabled him to produce a book which will prove invaluable to those who realise that the mere statement of the candle-power of a light offers no guide to its lighting effect, and that fifteen candles burning in different parts of a room give a very different illumination from one fifteen candle gas-jet burning in the chandelier.

The book very wisely is confined to the methods of distribution and measurement of illumination, and the portions dealing with photometry are more especially amplified in this direction, whilst all descriptions of systems of lighting have very properly been omitted.

The first chapter deals with the units and standards of candle-power, from the much-abused candle to the impracticable Violle melted platinum unit, but surely Mr. Trotter is a little unjust to the former when he says "the so-called English Parliamentary candle of spermaceti was not more scientific and hardly more accurate than the barleycorn of which three went to the inch." There are many photometricians of the old school who could assure him that the sperm standard candle, as made by Miller, when its use was guided by common-sense rather than by departmental directions, fell short of the modern standard in little else than convenience.

In the second chapter the author discusses "illumination and derived units," and it is pleasant to find due credit given to Sir William Preece, who, as early as 1889, recognised the necessity for a measure of illumination, and adopted the carcel-metre, to which unit he gave the name "lux," a name afterwards applied by the Geneva Congress in 1896 to the bougie-metre. The latter part of the chapter is devoted to a clear enunciation of the laws of light, flux of light, brightness, quantity, and reflection.

The distribution of illumination, more especially over a plane, occupies the next two chapters, and in the fifth photometers received full attention, and this chapter is of special value, as Mr. Trotter has introduced into it so much of his own work. It would have been even more interesting if he had criticised the various photometers from the point of view of the personal equation, as many observers would have liked to know his opinion of the Referees' table photo-

meter as compared with the open-bar disc photometer for general gas-testing work.

Several chapters are devoted to the minutiæ of photometric work, whilst in chapter ix. the measurement of illumination is dealt with, and another chapter describes the practical application of the methods employed, the work concluding with a valuable review of the subject of dioptric distribution of light.

The whole work is excellent from all points of view, and will form an addition to the engineer's and architect's library of far more than ordinary value.

MODERN GEOGRAPHY.

(1) *The Nations of the Modern World: an Elementary Study in Geography.* By H. J. Mackinder. Pp. xvi+319. (London: G. Philip and Son, Ltd.; Liverpool: Philip, Son, and Nephew, Ltd., n.d.) Price 2*s.*

(2) *A Geography of Ireland.* By O. J. R. Howarth. Pp. 224. (Oxford: Clarendon Press, 1911.) Price 2*s.* 6*d.*

(3) *Aberdeenshire.* By A. Mackie. Pp. x+198.

(4) *Huntingdonshire.* By the Rev. W. M. Noble. Pp. ix+152.

(5) *Worcestershire.* By L. J. Wills. Pp. ix+154. (Cambridge: University Press, 1911.) Price 1*s.* 6*d.* each.

(1) THE first of these works must not be regarded merely as a reading book for schools. It is, as its author observes, "a book of mingled geography and history," and contains so much matter that it was surely worthy of an index. While it develops the theme of three previous works, and brings out the bearing on human relations of the geographical conditions there described, it forms at the same time an independent treatise, which will stimulate the memory of many readers of full age. It is these, indeed, who will enjoy it thoroughly. A knowledge of modern history, and much of it obtained at first hand, is necessary for the complete appreciation of the changes of the map of Europe. Mr. Mackinder brings the older stages, such as those accompanying the Seven Years' War and the Napoleonic epoch, tersely and vividly before us. The later steps, the freeing of Venice, the partition of Lorraine, the uplifting of Bosnia, belong to our own eventful times. But we are led also to trace the rise of the United States and of Japan, and to take a large and scientific view of the inevitable expansion of Germany (p. 250), where men almost of our own blood are looking out also on the world. It may be somewhat ironic to suppose (p. 257) that the immense progress of Egypt under British organisation incited the Turks to improve their own home government; but the author's treatment of the British Empire as a whole forces a sense of responsibility upon the most insular and reluctant conscience. We may not like the reference nowadays (p. 258) to Japan and Turkey as "two heathen Powers," a phrase that has slipped in somehow from Mr. Mackinder's studies of the early nineteenth century; but his outlook is elsewhere that of the philosophic traveller. Under his direct and closely written sentences, we trace always that fine feeling for duty which is man's highest possession on this strange rotating globe.

(2) Mr. Howarth's "Ireland" is a welcome addition to the Oxford Geographies, a series edited by Prof. Herbertson. Aided by maps and excellent photographic illustrations, it brings the features of the country, grouped in natural regions, well before us. The author makes somewhat little (pp. 44 and 45) of Jukes's classic explanation of the courses of the southern Irish rivers, and seems to think that the Blackwater may have run against the face of an upraised fault-block at Cappoquin. Lamplugh's justly accepted explanation of the Scalp is neglected on p. 64, while the gorge of the Dargle is strangely described as having been deserted by its stream. Fig. 5, showing a drumlin-covered country backed by the Curlew Hills, is not so representative as it should be of "the Central Lowland," and the geological descriptions generally seem to date from the appearance of Hull's "Physical Geology and Geography of Ireland." We thus have Archæan granites (Fig. 3) opposed to large areas of "Cambrian and Silurian" strata in the metamorphosed regions; but the author himself must be held responsible for the insertion on his map of a Silurian district in the extreme south. Chapter xxvi. might be improved by an account of the cooperative organisation of agriculture, which has been largely aided by the fact that Ireland is a convenient and detached geographical unit. The publications of the Irish Department of Agriculture will assist Mr. Howarth in his next edition. The book has so many good points, and so clearly connects the structure of the country with the life of its inhabitants, that we hope it will meet with ready recognition.

(3) The county geographies issued by the Cambridge University Press, with their coloured physical and geological maps, and numerous landscape illustrations, have already taken a high rank. Aberdeenshire is largely a granite county, with solemn ice-worn highlands, and castles as stern as the jutting rocks along its coast. Mr. Mackie is a student of nature with a keen literary taste, and human interests and antiquities are evidently as attractive to him as are the birch-woods and the moors.

(4) The Rev. W. M. Noble's "Huntingdonshire" in the same series presents a very different country, where the fundamental rocks rarely appear from beneath the covering of glacial detritus and alluvial fenland. Too little emphasis seems to be laid (p. 31) on the high interest of the boulder-clay. The agricultural features, the great manor houses, and the stone bridges along the grand old highways are excellently illustrated and described.

(5) In "Worcestershire," Mr. L. J. Wills has a fascinating field. He describes the high ridge of Archæan granite in the Malverns, which rise on the western border like a blue wave against the evening sky. He illustrates the British formations up to the oolites of Bredon, and then directs attention to the upland vegetation of the Lickey Hills and the relics of old forests in the lowlands. The frosts in the hollows of the fruit-growing districts (p. 45) are, we presume, due to the creep of cold air downwards on still nights.

rather than to an increase in the amount of moisture present. A Severn coracle is figured (p. 87), and the antiquities lead us on to the stone houses of the Cotteswolds, and the unrivalled half-timber villages of the Trias plain. The chestnut-tree growing from a tomb in Kempsey Church (p. 140) may puzzle the reader who has not seen it. G. A. J. C.

MATHEMATICAL AND PHYSICAL CHEMISTRY.

(1) *Theoretical Chemistry from the Standpoint of Avogadro's Rule and Thermodynamics.* By Prof. W. Nernst. Revised in accordance with the sixth German edition by H. T. Tizard. (London: Macmillan and Co., Ltd., 1911.) Price 15*s.* net.

(2) *Higher Mathematics for Chemical Students.* By J. R. Partington. Pp. v+272. (London: Methuen and Co., Ltd., 1911.) Price 5*s.*

(3) *Abhandlungen der Deutschen Bunsen-Gesellschaft für angewandte physikalische Chemie.* Zweiter Band, Nr. v., Messungen elektromotorische Krafte galvanischer Ketten, mit wasserigen Elektrolyten. By R. Abegg, Fr. Auerbach, and R. Luther. Pp. x+213. (Halle a. S.: W. Knapp, 1911.) Price 8.40 marks.

(1) PROF. NERNST'S text-book occupies a special position amongst text-books of physical chemistry, written as it is by an author of such eminence as a pioneer and investigator in the science, and of such remarkable powers of exposition. From the chemical point of view no better basis for a work of the kind can be adopted than that of Avogadro's rule, for one of the main practical problems of the chemist is the determination of molecular concentrations. Gas densities, osmotic pressures, freezing and boiling points of solutions, conductivity of electrolytic solutions, and electromotive forces are all measured with this primary object in view, and therefore Avogadro's rule is at the root of them all. On this sound chemical basis, then, with the aid of the two laws of thermodynamics, the author has built. His ideas are always clear cut, his expression of them is always ordered and concise, and his mathematical proofs are of special neatness and brevity. It is no wonder, then, that although the book is scarcely intended for beginners, it should have reached a sixth edition in German and a third in English. The advanced student and teacher will specially welcome in this latest edition a detailed account of Prof. Nernst's new thermodynamical theorem, of which so much has been recently heard.

It is a matter for regret that the original English translation of Prof. Nernst's work was far from satisfactory, and so to a considerable extent spoiled the vogue of the book. The present translation has been revised and partly rewritten, and has without doubt been thereby vastly improved. But nothing short of complete retranslation could do justice to the original. However, an occasional awkwardly turned phrase of a distinctly Teutonic flavour will probably not greatly incommode the average reader, and so to all those who desire acquaintance with the facts and theories of physical chemistry and an indication of the lines of progress of the science, this translation of Prof. Nernst's excellent and unique work can be unreservedly recommended.

(2) Of all the mathematical books intended for the use of chemical students which have come under the notice of the present writer, Mr. Partington's is the most serviceable. The author has had a clear notion of the practical problem to be solved, and has performed his task successfully. He does not attempt to teach too much, and strictly adheres to what will be practically useful to the student of physical chemistry. Brief explanations of the nature of the mathematical processes employed are given, and their application is at once shown by well-selected examples. Thus convergent series are illustrated by the two examples of the washing of precipitates, and extraction from aqueous solution by means of ether; maxima and minima by the rate of catalysis of methyl acetate by water; the compound interest law by the decay of radio-activity; and so on. Alike to the chemical student who has no previous knowledge of the differential and integral calculus, and to the student who has learnt the methods of the calculus, but is at a loss how to apply them, this little book will be of considerable value.

(3) The Bunsen-Gesellschaft deserves the gratitude of those who work on the subject of electromotive force for the issue of the volume under review. It consists of three parts: (1) a complete systematic and chronological bibliography of measurements of electromotive forces; (2) a selection of the most trustworthy measurements reduced to a uniform system; and (3) tables of the most probable values of single electrode potentials.

In the bibliographical section the nature of the electromotive combinations measured is given, but not the numerical values obtained. Only aqueous solutions are considered, and such combinations as involve an agency external to the cell are excluded, *e.g.* thermoelectric and photoelectric combinations, d composition potentials, and the like. The arrangement is by elements according to the groups of the periodic table, both in the bibliographical and in the tabular sections; the single potentials are referred to the normal hydrogen electrode as zero.

With this book of reference at hand the worker at electromotive force can ascertain in the minimum of time what trustworthy work has already been done in his special branch, and see at a glance the most probable numerical values for any electromotive combination in which he may be interested. J. W.

OUR BOOK SHELF.

Field Note-book of Geological Illustrations. Arranged by Hilda D. Sharpe; containing 86 photographs and maps. Pp. 51. (Manchester: Flatters and Garnett, Ltd., n.d.) Price 3*s.* net.

THE idea of this book is a very happy one. Miss Sharpe has collected a number of photographs illustrating geological features, mainly from places in the British Isles, and Messrs. Flatters and Garnett are prepared to supply lantern-slides of most of them at 1*s.* each, or on hire at 1*s.* 3*d.* a dozen. Even as a supplement to the fine series issued by the British

Association, this selection is very welcome, and the book itself, at its modest price, is distinctly suggestive to the teacher. The illustrations, even when most effective, are rarely chosen from hackneyed subjects. We can scarcely do better than Stare Cove, Lulworth, or the Giant's Causeway, which naturally appear; but we can now avail ourselves of the limestone pinnacle of Pickering Tor, of eight views of the River Artro, near Harlech, from its source among the boulders to the sea, and of the Severn Valley in the Triassic plain of Worcestershire. Broad landscapes like the last have too often been neglected. Miss Sharpe gives us also the Silurian escarpments near Malvern, the rounded forms of the Longmynd, and the ice-worn gneissic floor of Sutherland. Details like an erratic near Harlech and pot-holes on the Gelt have also obvious uses. The subject may easily be extended into future volumes, if the enterprise meets with the success that it deserves.

A neat coloured geological map of the British Isles is given, but no useful purpose appears to be served by the insertion of tables of rock-forming minerals or of the classification of rocks, which cannot be regarded as either adequate or appropriate. The statements, moreover, made in this brief form are not always accurate. Opal is only partially described as "hydrated silica, brilliantly coloured." The term "glassy" applied to sanidine ought to have been long ago abandoned. "Carbonate of calcium" does not necessarily crystallise in rhombohedral crystals, since two forms are described below, one of which, aragonite, is here said to be triclinic. In the classification of the stratified rocks, "silica" and "silicates of alumina" are treated as minerals. These matters might be left with the text-books, to which the preface so properly refers.

Die Anzucht Tropischer Orchideen aus Samen. Neue Methoden auf der Grundlage des symbiotischen Verhältnisses von Pflanze und Wurzelpilz. By Dr. H. Burgeff. Pp. iv+90. (Jena: Gustav Fischer, 1911.) Price 3.50 marks.

It was announced by the French botanist, Noël Bernard, in 1904 that a symbiotic fungus inhabits the roots of many orchids, and that continued germination of the seed of such orchids is dependent upon the entrance of the fungus mycelium to renew the symbiotic union. This conclusion raised further problems, particularly whether the fungus differs in different orchids and how it may be isolated and inoculated. These are the practical points treated by Dr. Burgeff, who provides full instructions for raising seedlings in accordance with rigidly scientific principles. The methods are laborious. It is necessary to make pure cultures of the fungus, obtain aseptic seeds, mingle the two symbionts, grow them artificially, and transfer finally the young plant to natural conditions. The author also cultivated a number of mycelia taken from different plants with the view of distinguishing different varieties or species of fungus; the general result is indicated in a diagram showing that the mycelium of a given culture may serve for one, two, or rarely for more genera. Having thus shown how pure cultures should be made and described many experiments that he successfully carried out on these lines, he indicates a less troublesome method which consists in sowing the seed on sterilised fungus-infected soil.

It is unlikely that professional orchid growers will adopt either of the methods described, because it is in most cases an easy matter to raise seedlings under ordinary conditions by adding portions of the old roots or even soil from old cultures to the compost in the seed-pan. Nevertheless, the researches of Dr. Burgeff are theoretically and practically of great value, and should be carefully noted by growers, as they may serve to explain unexpected failures.

Elementary Applied Mechanics. By Prof. A. Morley and W. Inchley. Pp. viii+382. (London: Longmans, Green and Co., 1911.) Price 3s. net.

This book is intended for beginners of limited mathematical attainments, and, to meet the needs of such, extensive use is made of graphical methods and of numerical illustrations. Many worked-out exercises are included, together with others intended for solution by the student. Simple laboratory experiments are described. The standard is that of Stage I. of the Board of Education, and the method of treatment is quite orthodox. An introductory chapter on mensuration and measuring appliances is followed by chapters on elementary statical principles, leading up to the consideration of simple frames. Work, friction, and machines are then considered. Five very good chapters on the strength and elastic properties of materials are included, and the elementary laws of hydraulics form the subject-matter of the last three chapters.

The illustrations are clearly drawn, and are mostly correct. An exception occurs on p. 115, where a Prony brake is illustrated, having two mistakes in its design. In the chapters dealing with the composition and resolution of forces, it would have been better to omit the arrows shown on the triangles and polygons of forces. These cannot be shown on the force diagrams for frames, and a habit of inserting arrows which have to be omitted in subsequent diagrams is easier acquired than dropped by the beginner. We also observed several diagrams in which the resultant, found from the force diagram, has not been inserted in its proper place. The principal author is well known from his work on the strength of materials, and the present volume should take a good place among the other elementary text-books on the same subject already in existence.

The London University Guide and University Correspondence College Calendar, 1912. *Containing the Regulations for Examinations to be held in* 1912 *and* 1913. (London: University Correspondence College.)

The private student anxious to graduate at the University of London will find in this volume all the information he needs as to how to proceed. The best plan, in cases where it is possible, is for the student to enter one of the constituent colleges of the University and to follow the suitable course of study arranged for intending graduates; but for young men and women who are compelled to live far away from a college and whose time is occupied during the day, it would be difficult to find more helpful advice than this book contains.

Life in the Sea. By James Johnstone. Pp. vii+150. *New Zealand.* By Sir Robert Stout, K.C.M.G., and J. Logan Stout. Pp. viii+185. (Cambridge University Press, 1911.) Price 1s. net each.

Both these volumes belong to "The Cambridge Manuals of Science and Literature," a series which is fast becoming representative of every department of human knowledge. Mr. Johnstone provides a discussion of the general economy of the sea, in which the results of recent investigations of the microscopic life of the ocean are given due prominence. The object of the second book is to show faithfully in a brief way what New Zealand is and what has been done by her people, the treatment being such as is likely to appeal to readers who have not seen the Dominion.

These "Manuals" are not of the nature of primers

for young beginners; they are suitable, rather, for educated readers of maturer years, who desire to acquaint themselves with modern advances in the subjects in which they are interested.

L'Assaut du Pole Sud. By l'Abbé Th. Moreux. Pp. 221. (Paris: Jouve et Cie., 1911.) Price 1.50 francs.

THIS popular account of the various expeditions in Antarctic regions, arranged chronologically, will appeal to many readers. In English schools it might serve the double purpose of an interesting French text and leisure-hour reading in geography. The story is brought down to the present day and is illustrated, some of the pictures being views taken by Dr. Charcot on the *Pourquoi-Pas?*

Subject List of Works on Chemical Technology in the Library of the Patent Office. New Series, YN-ZB. Pp. iv+171. (London: The Patent Office, 1911.) Price 6*d*.

THE present list is concerned with oils, fats, soaps, candles, and perfumery; paints, varnishes, gums, resins, and india-rubber; and the paper and leather industries. With the volume, new series YK-YM, it supersedes "Patent Office Library Series, No. 7," published in 1901.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Late Sir Francis Galton.

I AM engaged on a memoir dealing with the life and work of the late Sir Francis Galton. He had a very wide correspondence, the width of which can only be appreciated by those who have seen the replies to his letters. Many of these are of great interest and value, and deal with important scientific problems. The main bulk of the letters start with 1885, although there are isolated letters from de Candolle, Speke, Buckland, Clerk Maxwell, and others from 1860 onwards. The letters from Francis Galton which led to these replies may still exist. May I appeal to any of your readers who have letters from Francis Galton to lend them to me for the preparation of this memoir? I should value especially any letters from 1850 to 1880; but all will be of value. Letters sent to me shall be carefully preserved, and returned if the owner desires it. Any letters which the owners are willing to present to this laboratory will be filed in the Galtoniana, which already contain many Galton manuscripts. KARL PEARSON.

Galton Laboratory for National Eugenics.

The Kaiser-Wilhelm Institut für physikalische Chemie und Elektrochemie at Dahlem, near Berlin.

ON October 1 Prof. F. Haber began his work as director of the new Kaiser-Wilhelm Institut für physikalische Chemie und Elektrochemie at Dahlem, near Berlin. The buildings of the institute, work upon which was begun during the summer of this year, are being erected by the Prussian Government working in conjunction with the "Koppel-Stiftung for the purpose of improving the intellectual relations of Germany with other lands."

The Koppel-Stiftung, which was founded in Berlin some years ago by Geheimer Kommerzienrat Leopold Koppel, and until now has maintained the German School of Medicine in Shanghai and the American Institute in Berlin, will provide the funds for the erection of the new institute, and will also give 35,000 marks annually for its maintenance during a period of ten years. The Prussian Government has provided the site, which is situated at the terminus of the new underground railway from the centre of Berlin to Dahlem, and has endowed the institute with the sum of 50,000 marks annually.

The institute will be controlled by a board consisting of two representatives of the German Government, two representatives of the Koppel-Stiftung, and the director of the institute. The director has an absolutely free hand in the choice of his work, his fellow-workers, and his assistants.

For the admission of investigators who wish to follow their own lines of investigation in the institute with their own means, the director must have the assent of the board of control.

The institute will consist of scientific and technical departments in separate buildings. The building of the scientific department is 600 square metres in ground area, and has a basement, entirely underground, containing constant temperature rooms. On the ground floor are the professor's laboratory and consulting room, the offices, the calibrating room in which are to be kept the necessary laboratory standards, the mechanic's workshop, and a lecture theatre to seat twenty-five persons. Further lecture-rooms are not provided in the building, as *teaching in the ordinary sense is not contemplated in the institute.* The first floor will be devoted to the library, chief assistant's room, glass-blowing room, and a laboratory for eight research men. On the second floor are the living rooms for the mechanic and his family, since the mechanic also acts as caretaker. This floor also contains rooms for photo-chemistry, for scientific collections, and workplaces for several more research workers.

The building is connected by a corridor with the technical department, the most important feature of which is the machinery hall, with a floor space of 200 square metres. This hall is surrounded by smaller rooms for chemical preparations, high-voltage and heavy-current work, and a blacksmith's shop. The ground floor of the technical building contains a consultation room and the laboratory of the assistant in charge of that department. On the first floor is living accommodation for two assistants and an engine-man, and also a room for the serving of refreshments.

The director's house will be erected in the grounds of the institute.

Although there exists no stipulation on the point, *it may be taken as a rule that, on account of the fact that no teaching as such is to be undertaken, only such students will be admitted by the director as have already finished their normal university course and desire a wider experience in scientific research.* There are no restrictions whatever as to the nationality of the men admitted by the director.

The director of the institute, Prof. Haber, was born in Breslau in 1868, and obtained his Ph.D. in Berlin in 1891. After obtaining his degree he spent several years partly in technical work and partly in securing further scientific training. In 1894 he went to Karlsruhe, and was appointed Privat-dozent in chemical technology in 18[illegible] and associate professor in 1898. In 1902 he was sent to America by the Bunsen Society of Applied Physical Chemistry to study the system of chemical instruction and the condition of electrochemical industries in the United States. In 1906 he was appointed to the post of professor of physical and electrochemistry in Karlsruhe, where he built up the best equipped research laboratory of physical chemistry in the world. Students from all parts of the world were attracted to this laboratory to such an extent that accommodation was insufficient to allow all of them to enter, even although Prof. Haber admitted as many as forty men at one time as research workers. What was most remarkable was that he personally directed the work of all these men, and often aided them in their experimental work. In 1907 he was called to take the place of Lunge in Zürich as professor of chemical technology, and in 1909 he was asked to undertake the control of one of the largest chemical works in Germany, but he declined both these appointments.

Prof. Haber introduced into Germany the rational method of instruction in elementary chemistry as embodied in the laboratory outline written by Prof. Alexander Smith. This book was translated into German by Prof. Haber and Fritz Hiller. The two books, "Lehrbuch der technischen Elektrochemie auf wissenschaftlicher Grundlage" (1898, now out of print) and "Thermodynamik technischer Gasreaktionen" (1905; English edition 1908), together with numerous contributions to the *Zeitschrift für Elektr*

chemie, *Wiedemann's Annalen*, and the *Zeitschrift für physikalische Chemie*, constitute his literary activities.

One of Prof. Haber's most important researches was that upon the ammonia gas equilibrium at high temperatures. This work resulted in the development of a commercial method for the manufacture of pure ammonia directly from the elements by the use of osmium or uranium as a catalyser. Another important series of researches was that upon the properties of flames, including the gas equilibria involved, the ionisation and conductivity of the gases, and the action of the ions as catalysers. He has spent much time during the last few years upon the study of the escape of electrons from the reacting surfaces of metals, and the effects of electrons upon gas equilibria and upon the velocity of chemical reactions. His other recent researches have been mostly upon the following subjects:—the electromotive force of the oxyhydrogen cell at high temperatures; the oxidation of nitrogen in the high-potential arc; a gas refractometer for the optical analysis of gases according to Rayleigh's principle; electrical forces at phase boundaries; the corrosion of iron by stray currents from street railways; the reduction of hydroxylamine; the use of solid materials, such as glass and porcelain, as electrolytes; the equilibrium between magnesium chloride and oxygen; electrode potentials and electrolytic reduction; the laboratory preparation of aluminium; the preparation of hydrogen peroxide by electrolysis; experiments on the decomposition and combustion of the hydrocarbons; and autoxidation.

The writer wishes to thank Dr. Fritz Hiller, of Berlin, for the greater part of the information contained in this letter. The statements in regard to the purposes and government of the institute are official.

WILLIAM D. HARKINS.

University of Montana, September 30.

The Weather of 1911.

THAT the year which is now drawing towards its close has been, as regards weather, a true *annus mirabilis* is a commonplace of conversation, and all the more so by reason of the contrast between this and last year. Not only has the summer been remarkable for its length, its heat, its brilliance, but the autumn, even since the weather was broken, has been characterised, unless I am mistaken, by an unusual tendency to relapse into bright sunshine: the storms have cleared up with great rapidity; the sunshine has been peculiarly clear, and mist and fog remarkably rare.

Now for these exceptional phenomena there must be some exceptional cause, or combination of causes. Can any of our meteorologists say what it is? I do not ask for a statement of causes such as the prevalence of anticyclones in a particular direction or the continuance of given winds, for such facts are only part of the phenomena to be explained; but I want to know whether any real cause can be assigned for the general character of the weather.

EDW. FRY.

Failand, November 8.

Dew-ponds in 1911.

THE pond near Chanctonbury, referred to by Mr. J. P. Eatworthy in NATURE of November 2 (p. 8), has generally been regarded as an ancient one; and I may perhaps direct attention to a statement in vol. lvii. of the "Sussex Arch. Collections" to the effect that it was made by the Rev. J. Goring, the father of the present owner. If this is correct, and the word "made" should not read as "re-made," there is, apparently, no ground for attributing the pond and its fortifications to Neolithic or any other ancient people.

A visit to St. Martinsell Hill, Wilts, on September 18 showed how disastrous had been the effects of the long drought. The pond near to the shepherd's cottage was dry except for a small circle of mud at the bottom. When normally full it could not have been more than 2 feet deep; and the whole area was strewn with loose angular flints. The occupier of the cottage stated that the pond had never previously dried up during the seventeen years he had been there. The sheep on the downs had nearly all gone, there being no "feed" for them. In short droughts the dew seems to be sufficient to maintain the "feed"; but this year the absence of rain for so long brought about a remarkable absence of dew, and the dependence of dew upon earlier fallen rain seems to be an established fact.

Another pond is to be seen about a quarter of a mile to the north of the cottage on level ground. It has a large hole in the centre some 5 feet deep. This pond was quite dry. A quantity of puddle had been removed from the depression.

Another pond-depression occurs south-west from the cottage and barn, at the beginning of the spit of down which here juts out over the low-lying land of the Vale of Pewsey. It is grass-grown, and has several Scots pines growing in it. There is no good reason to think it was a "quarry," or even a "tally-house," as has been alleged. It was dry.

Further west along this narrow spit of land, and beyond the great ditch and vallum known as Giants' Graves, is an empty pond-depression about 20 feet across, constructed in a most convenient position if only it had water. It has apparently been grass-grown for many years—another instance of the extraordinary neglect of modern-day farmers.

All these ponds were circular. On descending on the east of St. Martin's Hill towards Wootton Rivers, past a series of mounds like swellings on the side of the hills, called by some authors "pit-dwellings," I noticed a square pond at the edge of a field. This was also dry. But a little nearer Wootton Rivers, at the side of the road, was a pond full of water. This was on the low ground beneath the hills; and the secret of its success lay in the fact that it was almost surrounded by tall trees, some of which completely overhung the pond. Thus evaporation was reduced to a minimum in the heat of the summer sun, whilst it may have been replenished by the condensation on the leaves of the trees.

It was observed that a concrete pond was being built on a slight eminence in a field near at hand, and it was stated in the village that a boring was being made for water.

There is a moral. In the first place, farmers do not make their ponds deep enough. In the next place, they neglect them until they dry up. Finally, when they do repair them, they remove the puddle at the bottom in the process of cleaning, and then wonder why the ponds fail to hold water.

EDWARD A. MARTIN.

The Research Defence Society and Anti-Vivisection Shops.

WE desire to make a special appeal for the purpose of undoing the harm which is done by anti-vivisection shops and processions. The exhibits in these shops are of a most misleading nature: and the truth as to anæsthetics is carefully concealed. No operation, more than the lancing of a vein just under the skin, is allowed to be done on any animal in this country, unless the animal is under an anæsthetic throughout the whole of the operation.

It will be remembered that one of these shops, on the death of H.M. King Edward VII., distributed a leaflet suggesting that his Majesty's death was due to medical treatment.

We have, of course, received many complaints against these shops. We find that the police have no power to close them: and we can only place men outside them, to give our leaflets to passers-by.

But this constant giving of literature is a heavy expense to our Society. We therefore appeal for special contributions toward this purpose. We make this appeal with confidence, for we are sure that the public recognises the grave harm which is done by these shops, especially to children. All contributions should be sent to the Hon. Treasurer, Research Defence Society, 21 Ladbroke Square, London, W.

We may, perhaps, take this opportunity of mentioning that a letter has just been received from Sir Apolo Kagwa, K.C.M.G., the Prime Minister of Uganda. It is dated from Mengo, Uganda, September 26. "I really think," he says, "that in a few years' time sleeping sickness will be extinct in Uganda, and people will become immune from

the disease." If this happy result is obtained it will, without doubt, be due to the work done by the Royal Society Commission, who gained their knowledge on the subject by experimentation on animals.

The Definition of Mass.

IN NATURE for October 26 your reviewer, in criticising "An Elementary Text-book of Physics," writes:—

"In common with so many other text-books on this subject, this book lacks the fundamental definition of 'mass.' The author introduces the term 'mass' without definition in order to define force, and then uses this definition for the purpose of defining mass. Few writers on mechanics appear to realise that a definition of mass *apart from force* is the essential first step from the point of view of absolute measurement."

I am not concerned to defend this particular text-book, of which I have no knowledge, but I should be grateful, in common with many of your readers, if your reviewer would give us a satisfactory definition of mass *apart from force* (the italics are his own). I presume he would not be content with the fatuous statement that "Mass means quantity of matter"! Apparently Sir Oliver Lodge must be included amongst those censured, for in his "Elementary Mechanics" he writes:—

"We see, then, that mass is measured, and must be held to be defined, by the property of inertness possessed by matter—that is, by its requiring force to move it if at rest, and to stop it if in motion."

The same view is expressed by Clerk Maxwell in his invaluable little book "Matter and Motion," article xlvi.

Let us be frank about this question. The idea of force, like the idea of temperature, is derived from our bodily sensations, and is therefore suspect in some quarters. It is said that our sensations are not trustworthy. Nevertheless, we can form from them by long experience fairly accurate estimations both of force and temperature. To measure temperature we generally observe the expansion of a material body. To measure force we can use the deformation produced by it when acting on some portion of matter—the statical method; or we may measure the acceleration produced in a particular body—the dynamical method. The two methods give concordant results. We observe the effects of changes of temperature; we infer the passage of "heat" from one body to another. We observe the effects of force in producing acceleration. We find that the ratio of force to acceleration (or, what is equivalent, the ratio of impulse to change of velocity) is (approximately) constant for a particular body. We infer the existence of "mass," which is simply the value of this ratio. To say that "mass" is indestructible is to affirm that this ratio remains constant through the range of our experiments. If we extend the range we are led to believe that the ratio is no longer constant when the velocity of the body approaches the velocity of light.

H. S. A.

IT gives me much pleasure to comply with "H. S. A.'s" request expressed in his letter, but, at the same time, I should like to refer him to chapter iii. of Porter's "Intermediate Mechanics" for a clear and exact statement with regard to this question.

In the first place, it should be pointed out that definitions are of two kinds, qualitative and quantitative, and it was in the latter sense that the term was used in that portion of my review which "H. S. A." quotes. To the definition due to Lodge, regarded as purely qualitative, no objection is offered; it is when *quantitative* definitions are required for the purpose of measurement that the difficulties arise. Surely it is obvious that it is meaningless to define unit force as that which produces unit acceleration in unit mass, and then to define unit mass as that which acquires unit acceleration under the action of unit force. Of course, if we are content to define force in terms of the deformation it produces in a given piece of material, mass may then be measured in terms of force and acceleration; but the system of units arrived at will not be absolute. To obtain absolute units, we must be able to compare either two forces or two masses by measurements of space and time alone. The problem of defining mass quantitatively therefore resolves itself into defining the *ratio* of two masses in terms of space and time. This may be done as follows.

Let two masses m_1 and m_2 be isolated (a state of affairs approximately realised in Hicks's balance), and let them interact in any way. Let their accelerations at any instant be a_1 and a_2 respectively. These will be oppositely directed. Then the ratio of the masses is defined as being numerically equal to the inverse ratio of the accelerations, or

$$m_1/m_2 = -a_2/a_1,$$

the negative sign expressing the fact that the accelerations are opposed in direction. We may prove that the definition is valid by extending the experiments to a number of masses taken in pairs, and finding that the results are consistent. The unit of mass may now be fixed, and that of force defined in terms of it. Further, it may be pointed out that as consequences of the experimental verification of the validity of the above mode of definition, the principles of the equality of action and reaction, and that of the conservation of momentum, immediately follow.

From this point of view, therefore, we regard force as being a mass-acceleration rather than mass as the ratio of force to acceleration. The thermal analogy of Dr. Allen, if extended, suits the argument excellently. We do not obtain an *absolute* scale of temperature until we make it independent of any particular substance; neither are we able to measure force absolutely until *its* scale ceases to depend upon the behaviour of any special body under its action.

THE REVIEWER.

Altitude and Animal Development.

SOME time ago I found in the alluvium of a little Derbyshire stream a tubificid of a species and genus new to Britain. It was characterised by its large lymph corpuscles and its Pachydrilus-like form, on which account it was named *Meganympha pachydriloides*, Friend. The description showed that the animal possessed an average of forty-five segments, three or four forked setæ like Limnodrilus, a brain deeply lobed behind, spermathecæ pear-shaped or globular, and a penis-sheath, or large penial seta. While working out some species of Fridericia a few days ago, and turning to Bretscher (*Revue Suisse de Zoologie*, 19[…]) for some details, my attention was directed to his description of *Rhyacodrilus falciformis*, and it appeared evident that the Derbyshire worm was one with the Swiss.[1] But Bretscher states that the alpine forms have only thirty segments. Issel, de Ribaucourt, and Bretscher have recently given us many facts to show that annelids of the same species are very much smaller when found high up in the Alps than when found in the valleys. The foregoing seems to be an interesting confirmation of these statements.

But I find that other factors are at work. It is many years since Vejdovsky first described the little annelid known as Achæta, on account of the absence of setæ, but it is only within the last few months that specimens have been found in England. Southern found three different species in Ireland two years ago, and I have found the same number, though differing in kind, in England. Now Vejdovsky gives 15 mm. as the length of *Achæta bohemica*; but Southern says that though the Irish specimens agree with the Bohemian in other respects, they are but 5–6 mm. in length. In August I found *A. bohemica* Vej., in Kew Gardens, and the length agreed with the Irish forms. On November 7 I took the same species from a little grass plot in the heart of the city of Nottingham, and the specimens again measure 5–6 mm.

It seems easy to account for the difference in size in the case of Rhyacodrilus; but can any zoologist or biologist suggest an explanation of the difference between the Bohemian and British forms of Achæta?

HILDERIC FRIEND.

110 Wilmot Road, Swadlincote, Burton-on-Trent.

[1] Since writing the above I have discovered that Rhyacodrilus was described in 1904 by Ditlevsen as *Ilyodrilus filiformis*. He was familiar with Bretscher's work, but did not observe that the Danish tubificid had already been diagnosed.

RECENT THEORIES OF VOLCANIC ACTION.[1]

FIFTY years ago it appeared as though the volcanic problem had been completely and satisfactorily solved. Granted a cooling globe in which a solid crust covered heated matter, actually or potentially liquid, then the influx of sea-water through fissures in the crust seemed to account for all the phenomena observed during a volcanic outburst. Observations had then been almost wholly confined to the small group of Mediterranean volcanoes; but as our knowledge of volcanic action and terrestrial physics has grown with more continuous study over wider areas, these conclusions, as well as the premises on which they were based, have long since failed to satisfy students of geophysics.

One of the chief factors in bringing about this revolution in opinion has undoubtedly been the systematic study of the remarkable volcanoes of the Hawaiian islands, for which we are especially indebted to the geologists of the United States. In the great "pit-crater," or "sink," of Kilauea, always open to inspection, we find the explosive action and escape of gases reduced to a minimum, such "sinks" presenting the most marked contrast to the explosion-formed craters of Vesuvius and Stromboli (see Figs. 1 and 2). Equally striking is the difference between the great flat Hawaiian domes, rising above the ocean-floor to the height of the Himalayas, with slopes of from 1° to 4°, and the steep conical piles of Chimborazo and Cotopaxi. Another volcano of the same type as the Hawaiian, Matavanu, in the Samoan group, has been recently described by Dr. Tempest Anderson and other observers. In the study of the highly heated lavas of these volcanoes, an explanation has been found of the "slaggy" and "ropy" varieties of lava, as well as of the peculiar types known as "pillow-lavas" formed when they flow into the sea (see Fig. 3).

Photo.] [*E. Moses, Hilo.*

FIG. 1.—Panoramic photograph of Halemaumau (the open lake of lava in the crater of Kilauea) on January 13, 1910, with Mauna Loa in the background. The nearly circular lake was about 200 metres in diameter; its surface was estimated to be about 25 metres below the rim of the crater.

Photo.] [*E. Moses, Hilo.*

FIG. 2.—Panoramic photograph of Halemaumau on February 20, 1910. The lake level fallen about 30 metres below the surface of the "black ledge" of Kilauea in the foreground.

In addition to the new light thrown on volcanic action by the observations carried out in recent years on these Pacific volcanoes, there have been, during the last thirty years, three great outbursts of igneous activity, attended by phenomena of startling and unexpected character, which have served to awaken geophysicists to the fact that the old and simple theories formerly accepted stand in need of revision or replacement.

In 1883 the tremendous outburst of Krakatoa, in one of the great highways of the world's commerce, supplied opportunities for the study of the *explosive* type of volcanic action, which is so strikingly different from the *effusive* type of Hawaii and Samoa. Without any outflow of lava, fused matter was shot to the height of from sixteen to twenty-five miles into the atmosphere, the shocks producing air-waves that travelled two or three times round the globe. In this great uprush of gases, the molten materials were reduced to such a state of fine division that they were diffused through the whole of the atmosphere of the globe, giving rise to those wonderful sunset glows that will be so long remembered. In this great outburst, the hydrosphere was affected to a much less extent, and the lithosphere scarcely at all—for earthquake shocks, as distinct from air-concussions, were almost, if not entirely unfelt.

Five years later, in 1888, occurred the singular eruption of Bandaisan in northern Japan. In this case the sudden outburst of gases did not carry with

[1] "The Nature of Volcanic Action." By Reginald A. Daly. Proceedings of the American Academy of Arts and Sciences, vol. xlvii., No. 3, pp. 47–122, June, 1911. (Boston, Mass.)

it any molten materials, but was sufficiently violent to throw down one side of a volcano more than 6000 feet high, which had been long in the "Solfatarra

Photo.] [*T. Anderson.*

FIG. 3.—"Pillow Lava," formed by the molten material coming in contact with sea-water. The chilled surfaces form a scum which is stretched and distended by the still liquid material forced forward behind, into the great pillow-like masses shown above.

stage." The quantity of material thus displaced was calculated by Profs. Sekiya and Kikuchi, the commissioners appointed by the Japanese Government to investigate the phenomena, to be no less than 2782 millions of tons! European geologists had long been familiar with the fact that among the miniature volcanoes of the Eifel district there are examples in which scarcely any ejection of igneous matter has taken place, the vents being surrounded by fragments of slate and other underlying rocks; and the experiments of Daubrée and Sir Andrew Noble have shown that heated gases, under intense pressure, are capable of drilling holes through the hardest rocks. But in the case of Bandaisan, the "hurricane-blasts" hurled along the *débris* at the rate of forty-eight miles an hour, the hurtling masses of which were gradually reduced to the condition of sand, and covered an area of twenty-seven square miles. Although "steam" is said to have been seen rising to the height of 4200 feet above the "crater," the materials overwhelming the country were dry, except where they crossed lakes or rivers. But towards the end of the eruption scalding mud is said to have fallen and destroyed many lives; it is noteworthy, however, that a survivor declared that the gases in which he was enveloped were not of a poisonous character. From the direction in which the materials were thrown, there is some ground for the belief that the outrush of gas was not, as in Krakatoa, vertical in direction, but more or less oblique. The result of the eruption was to produce a great cavity which strikingly resembles the Val del Bove of Etna and the Caldera of Palma.

In 1902 there occurred, in the West-Indian islands of Martinique and St. Vincent, extraordinary outbursts of volcanic violence, which were carefully studied by English, French, and American geologists. In these cases the great destruction of life and property was caused by enormous volumes of superheated gas, charged with solid particles of all sizes, which rushed down the valleys leading from the mountain summits to the sea. These mixtures of gas and dust behaved like liquid torrents, and travelled at a rate of more than eighty miles an hour, sweeping everything before them. Their destructive action on living beings appears to have been in part due to the heated condition of the gas and in part to its suffocating character. In Martinique another very curious phenomenon was exhibited: the mass of molten rock consolidating in the vent of the volcano was gradually pushed up by forces from below until it formed a great "spine" which attained an elevation of nearly 1200 feet; but after many changes, due to both movement and disintegration, extending over more than a year, this "spine" finally disappeared (see Fig. 4).

It has generally been assumed by geologists that the chief component in the gas emanations—alike in Krakatoa, in Bandaisan, and in Martinique—was water gas; and this seemed to be indicated, not only by the vast clouds overhanging volcanic vents, but by the torrents of rain which, mingling with finely comminuted rock, gave rise to the "muddy lavas" often so much more destructive than the "fiery lavas" of active volcanoes. It is true that deposits of chlorides, sulphur, and other products around volcanic vents indicate the presence of various other gases in the uprising columns, but these have usually been regarded as quite subordinate to the high-pressure steam to which the most important action in volcanic eruptions has usually been attributed.

Photo.] [*E. O. Hovey*

FIG. 4.—The great "spine," composed of andesitic lava, which was forced up during the eruption of 1903 to the height of nearly 1200 feet above the crater-rim of Mont Pelée in Martinique.

It has long been known that lavas after their consolidation are found to contain, occluded in their

mass, gaseous matters which are given off when the rock is heated. This is especially true of lavas of a glassy character, which when fused have been shown to swell up into masses of pumice of many times the dimensions of the glass from which it is formed. M. Albert Brun, of Geneva, has collected and analysed the gases given off in such cases, and finds them to be nitrogen, ammonia, chlorine, hydrochloric acid, carbonic acid, and various hydrocarbons. Reasoning from these and other observations, he has been led to the conclusion that steam, instead of playing the most important part in volcanic eruptions, must be regarded, in many cases at least, as only an adventitious and accidental accompaniment of them. He has certainly shown grounds for the more thorough investigation of the nature and composition of these mixed gases, which, as recent studies have shown, play such an all-important part in volcanic outbursts.

But in addition to the more exact and systematic studies which have been made of the great volcanic eruptions in recent years, there is another class of researches which have supplied evidence of at least equal value concerning the nature and origin of these phenomena.

The study of rocks in thin sections under the microscope has shown that the two classes of rocks known as "plutonic" and "volcanic" respectively are essentially identical, and pass into one another by insensible gradations. Great areas of crystalline rocks ("batholites") and lake-like intrusions of similar materials ("laccolites"), lying in the midst of sedimentary and other rocks, were probably the roots of the volcanoes of previous periods in the earth's history. In these cooled reservoirs we may study the changes which have taken place in the magmas that have supplied the old volcanic vents, and—inverting the Lyellian principle—we may reason concerning the processes which must now be going on beneath existing volcanic vents from what we can prove to have taken place beneath those of former geological periods. Nor are there wanting examples of ancient volcanoes, dissected by the scalpel of denudation, which illustrate the intimate connection which exists between the plutonic and volcanic rock-masses.

The author of the memoir before us is well known to geologists by a number of valuable memoirs dealing with the evidence of changes which must have taken place in the great underground reservoirs of igneous rocks. These he has had the opportunities of investigating while engaged as a Canadian member of the International Boundary Surveys. More recently, he has had the opportunity of making a detailed investigation of the phenomena exhibited in the Hawaiian volcanoes. His outline of "a general working theory of vulcanism" is the result, as he tells us, "of the writer's studies in the Hawaiian Islands in 1909, but many of the chief conclusions are founded on his field-work in plutonic geology, as well as on the geology of many ancient volcanic formations."

That the hypotheses he now formulates are of a somewhat speculative character, and that many of his conclusions are more or less tentative, Mr. Daly fully admits; but that, nevertheless, his memoir is an important contribution towards the solution of a very difficult problem everyone will agree. He summarises his suggestions as a "substratum-injection hypothesis," believing that the surface phenomena can best be accounted for by abyssal injections of a deep-seated basaltic magma through an acid substratum of granitic or gneissic rocks everywhere underlying the sedimentary formations. But in elaborating his theory the author is led into a number of discussions of points of extreme interest and importance, and, even if his main conclusions are rejected, these subsidiary discussions retain their suggestiveness and value.

It is admitted by the author that the conditions leading to his "abyssal injections" "form a subject of great theoretical difficulty"; he apparently accepts the view that the high temperatures underground are due to the earth being a cooling globe, although he admits the influence of various chemical reactions in augmenting, locally, these high temperatures. The chief argument in favour of the view that the earth's interior is in a highly heated, if not molten, condition is, of course, derived from the fact that observations made in mines, tunnels, wells, and bore-holes everywhere indicate a progressive rise in temperature as we go downwards. Nevertheless, the most recent observations of underground temperatures have revealed such startling discrepancies between the results obtained in different areas—discrepancies that, it seems, are quite incapable of being explained by differences in the conductivity of rocks and similar causes—that the argument for a "molten globe" based on underground temperatures loses much of its force, and with it must go the estimates of the earth's age that have been based upon it. In these circumstances, the thoughts of geologists turn, not unnaturally, to the great revelation of radio-activity as a source of heat, for here may possibly be found the means of removing, to some extent at least, the "theoretical difficulties" which, the author admits, still beset the explanation of those deep-seated actions for which he argues.

J. W. J.

SPANISH OBSERVATIONS OF BROOKS'S COMET (1911*c*).

BROOKS'S comet has recently been a conspicuous object, and no doubt a great number of valuable observations have been made, both photographically and visually, at most of the observatories in the northern hemisphere.

Some very interesting records have recently been received from Señor F. Iniguez, the director of the Madrid Observatory, and not only do these include photographs of the comet itself, but an excellent spectrum accompanied by a list of the wave-lengths of the bands recorded.

The photograph showing the form of the comet was secured on September 28, with a 6-inch Grubb doublet, during an exposure of one and a quarter hours (9h. 15m. to 10h. 30m.), the comet then being of the second or third magnitude. This photograph is reproduced here (Fig. 1), the scale being 1 mm. to 5 minutes of arc. On this date the tail stretched to a distance of 15 degrees, and consisted of delicately fine interlacing filaments; the nucleus with its surrounding nebulosity measured 21 minutes in diameter. Spectroscopic observations were made visually with a slit spectroscope, and photographs were secured with the Grubb photographic equatorial, having an objective prism of 20 cm. aperture and 20° refracting angle. These have shown the spectrum to consist of seven images of the nucleus. The visible bands are the three situated at the red end of the spectrum, and these form three distinct spectral bands, while the sixth is composed of fine lines. The seventh appears double, although its components are not well defined and were measured as single.

The wave-lengths have been determined by Señor Iniguez from four plates taken on September 19, 20, and 26. The three visual monochromatic images of

the nucleus are λ 555, 514, and 472. The fourth band is made up of the lines λ 440, 434, and 432, and the wave-length of the fifth is λ 423. The sixth band he finds to be composed of the lines λ 410, 407, 405, 404, and 402, while 388 he gives as the wave-length of the seventh band. By using a prismatic camera, the spectrum of the comet's tail has also been secured, but because of its faintness only monochromatic images of the tail in the three visible bands were

FIG. 1.—Brooks's Comet as photographed on September 28 at the Madrid Observatory with an exposure of 1½ hours.

recorded. The whole length of the spectrum indicates the presence of a faint continuous spectrum. This spectrum was secured on the night of September 26 with an exposure of two hours (9h. to 11h. G.M.T.). Besides a paper print of this spectrum, a drawing with a scale of wave-lengths also accompanies the communication. This drawing is reproduced here (Fig. 2), but the violet has been placed on the left-hand side to conform with the general adopted procedure.

the chief carbon bands being strongly developed, it is very probable that the Madrid spectrum represents bands and lines of the same substances. No doubt in the near future spectrum observations, both photographic and visual, made at other institutions, will be soon forthcoming, so it will be interesting to see if the same explanation of the origin of the bands is corroborated.

W. J. S. LOCKYER.

CONFERENCE ON THE THEORY OF RADIATION.

A VERY successful meeting was held in Brussels from October 29 to November 4, to discuss the present position of the theories of radiation and of molecular theory in general. The following were present at the meeting:—Profs. H. A. Lorentz, Kamerlingh Onnes, W. Nernst, M. Planck, Rubens, Sommerfeld, W. Wien, Warburg, Brillouin, Mme. Curie, Langevin, Perrin, Poincaré, Einstein, Hasenöhrl, Martin Knusden, J. H. Jeans, and Rutherford, while Dr. Goldschmidt, of Brussels, Dr. de Broglie, of Paris, and Dr. Lindemann, of Berlin, acted as secretaries.

The inception of this "conseil scientifique" was due to Mr. Ernest Solvay, of Brussels, who very generously offered to defray the expenses of the conference and the cost of publication of the papers and discussions contributed at the meeting. The members were the guests of Mr. Solvay at the Hotel Metropole, and with the exception of one meeting at the Physiological Institute, founded by Mr. Solvay, the meetings took place in one of the reception-rooms of the hotel. The arrangements of the meeting were under the charge of Dr. Goldschmidt, who was indefatigable in looking after the comfort of the visitors. Prof. H. A. Lorentz was president of the "conseil scientifique," and the success of the meeting was due in large measure to his able management.

The following papers were read before the congress:—Sur l'application au rayonnement du théorème de l'équipartition de l'énergie, by Prof. H. A. Lorentz; a short communication in the form of a letter from Lord Rayleigh; the kinetic theory of specific heats, by Prof. J. H. Jeans; die Gesetze der Wärmestrahlung und die Hypothese der elementaren Wirkungsquanten, by Prof. Max Planck; die Bedeutung des Wirkungsquantums für unperiodische Molekularprozesse in der Physik, by Prof. Sommerfeld; zum gegenwärtigen Stande des Problems der spezifischen Wärme, by Prof. Einstein; Anwendung der

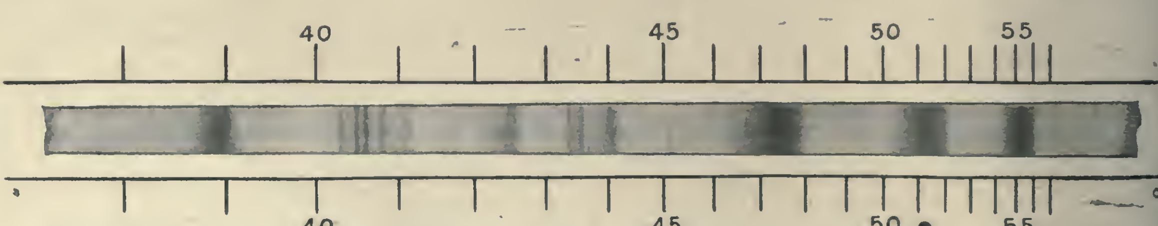

FIG. 2.—Spectrum of Brooks's Comet drawn from a photograph taken at the Madrid Observatory.

The writer has made a comparison of this spectrum with that which was taken of comet 1907*d* (Daniel) by Prof. Campbell. While the latter spectrum is on a very much larger scale and rich in detail, it is seen nevertheless that both are very closely identical when allowance is made for the smaller scale. As Daniel's comet was stated by Campbell to show no radiations other than those due to carbon or carbon compounds,

Quantentheorie auf eine Reihe physikalisch-chemische Probleme, by Prof. Nernst; les preuves de la Réalité Moléculaire, by Prof. Perrin; die kinetische Theorie der ideale Gase und die Versuchsresultate, by Prof. Knusden.

A vigorous discussion took place on each of these papers, an abstract of which will ultimately be published. Special interest was taken in the papers deal-

ing with the question of specific heats. Prof. Nernst gave an interesting account of the experiments upon the variation of specific heat with temperature down to low temperatures and of their explanation in terms of the "quantum" theory proposed by Prof. Einstein.

The meeting took place under unusually pleasant social conditions, for all the members were staying at the same hotel and dined together. The interchange of views on many problems of modern physics was a feature of the occasion, and led to a much clearer understanding of the points at issue.

At the close of the meetings, Mr. Solvay invited the conference to meet again in Brussels in 1913.

E. RUTHERFORD.

SIR SAMUEL WILKS, BART., F.R.S.

SIR SAMUEL WILKS, at the time of his death, on November 8, the senior fellow of the Royal College of Physicians of London, was born at Camberwell on June 2, 1824. He was the second son of Joseph Barber Wilks, treasurer to the East India Company, who himself had many ancestors in the service of that company. He was educated at Aldenham. In 1840 he was apprenticed to a family doctor at Camberwell, Mr. Richard Prior, whose widow he subsequently married. He began to attend lectures at Guy's Hospital in 1841, and took the M.D. London in 1850. He earned many distinctions at the University. In 1856 he became a fellow of the College of Physicians, and assistant physician to Guy's Hospital, in 1867 full physician; in 1870 he obtained his F.R.S., and in 1897 his baronetcy. He was president of the Royal College of Physicians from 1896 to 1899, and he was a governor of Guy's Hospital.

Wilks began work at a period when most doctors were satisfied with vague words that meant little; hence his desire to know the causes of things was at that time remarkable, and led him to be the first to make systematic post-mortem examinations whenever he could. When he gave up his work in the post-mortem room, he had made more post-mortem examinations than anyone alive except Virchow. In the course of these he found that syphilis could affect internal organs. As now we know that several internal diseases are due to it, this was a most important discovery. The original paper, entitled "On the Syphilitic Affections of Internal Organs," was published in the "Guy's Hospital Reports" for 1863. Of it in later years Wilks wrote, "I regard this as the most noteworthy and original article it has been my good fortune to write."

He was a great observer, and was the first to point out that excess of alcohol causes paralysis of the limbs, and that atrophic lines may form on the skin apart from stretching of it; he described and named the condition of the knuckles called "verruca necrogenica," and under the name of arterial pyæmia he described what is now known as malignant endocarditis; also he did much to establish firmly that Bright's disease, Addison's disease, and Hodgkin's disease were distinct entities. The last he discovered independently, but found that Hodgkin had given an account of some examples of it, and accordingly Wilks gave the name Hodgkin's disease to it.

All Wilks's investigations were done at Guy's Hospital, and he greatly added to the reputation of its medical school. His strong personality and his enthusiasm for the advancement of medical knowledge made him much beloved by students, and by his influence many were stimulated to take an interest in their work as an intellectual pursuit. He was always the champion of investigators, and was one of the most energetic in forming the Society for the Advancement of Medicine by Research. His mind was extraordinarily active even when well advanced in years. He did not retire until he was seventy-seven years of age, and then, when he went to live at Hampstead, he was, at the age of more than eighty, president of the Hampstead Scientific Society, and read papers before it.

His "Pathological Anatomy," first published in 1869, has gone through three editions. It has become one of the medical classics, and is still the best book on the subjects of which it treats. It has been well said that if you think you have discovered a new fact in morbid anatomy, you will find it was observed by Wilks and is mentioned in his book. Students were so much attracted by the matter of his lectures that at their request they were published, and form his two other books, "Diseases of the Nervous System" and "Specific Fevers and Diseases of the Chest."

W. H. W.

MR. JOHN BROWN, F.R.S.

THE death of Mr. John Brown, which, as announced in last week's issue, occurred at Belfast on November 1, removes one who was a scientific amateur in the best sense of that term, and whose enthusiasm bore fruit in much solid work in the department of physics in which he was specially interested.

Born in 1850, the son of a prominent linen merchant, in the north of Ireland, Mr. Brown, after a very short experience of business life, retired from the firm which bears his father's name in order to devote himself entirely to the scientific and engineering pursuits for which his bent had been clearly shown from boyhood. He soon became absorbed in electrical matters, particularly in the question of Volta contact electricity, about which then and since so much controversy has been carried on. His first paper on the subject was published in *The Philosophical Magazine* in 1878, and was followed by a series of others in which he detailed the results of his experiments and lent important support to the chemical theory of these phenomena. The work was done largely by means of home-made apparatus, and gave evidence of experimental ingenuity and carefulness of a high order. He maintained that the effects were due to films of condensed vapour or gas on the surface of the metals, and regarded the pair of metals in contact as equivalent to a voltaic cell, divided in the electrolyte, and having the amount of electrolyte reduced until only an invisible film remains on each plate. In support of this theory he tried the effect of surrounding the metals by different gases, and obtained variations in the value of the potential difference, the proper interpretation of which was a matter of some controversy.

Mr. Brown was elected a fellow of the Royal Society in 1902, and in the following year he published what proved to be his last contribution to the voltaic question. In this he claimed to have got rid of the gaseous films by heating the plates to a high temperature in a bath of petroleum, when the difference of potential was found to disappear. Before his death he had planned to repeat this crucial experiment with additional precautions during the present winter.

His other publications of pure scientific interest were in connection with the allied question of electrolytic conduction. On this he took up a position strongly hostile to the modern developments of the dissociation hypothesis.

Mr. Brown was much interested in mechanical and engineering matters, especially in connection with motor engineering, on which he did some pioneering

work. This led him to study the question of road-making and road-testing, and he devised an ingenious instrument, called the viagraph, which gives a trace of the contour of the road-surface and a numerical value for its "bumpiness."

Mr. Brown will be much missed in Belfast, where he did a great deal to kindle and keep alive scientific interests in the community, and where his personality and ability won him much influence and popularity.

W. B. M.

THE SOLAR PHYSICS OBSERVATORY.

THE *Cambridge University Reporter* gives an account of the action taken by the Council of the Senate on this subject. None of the scientific questions we referred to in the article in last week's NATURE are touched upon, including the all-important question of the site, and the dismissal of the staff which for the last thirty years has done work which has received world-wide approval, on a programme which has been followed in the newer institutions.

One of the points insisted upon is how the University is to find the 600*l.* a year, representing a capital sum of 15,000*l.* or 30,000*l.*, according as we reckon the interest at 4 or 2 per cent., which the Treasury demands in return for the capital sum of 5500*l.* to be inserted in the estimates for the new installation.

We confess we look with dismay upon the proposal. We trust the Senate will well consider it in all its bearings. It is not the fault of the Senate that Cambridge can never be a fit site for an observatory occupied in the work demanded by modern physical inquiries, but it will be its fault if it acts as a cat's-paw of the Treasury in aiding the detachment of national scientific work from the direct control of a Government spending department with a voice in the Cabinet; in agreeing to administer the needs of a rapidly growing branch of science for a fixed sum based only on the present needs; and in endorsing the view that its future alumni when appointed directors of national observatories are sufficiently remunerated by a stipend of 200*l.* a year.

NOTES.

IN reply to an inquiry as to the award of the Nobel prizes, Prof. Svante Arrhenius has kindly sent us the following information:—(1) *Prize for medicine:* awarded on October 21, the birthday of Dr. Alfr. Nobel, by the Carolinian Institute (faculty of medicine) in Stockholm to Dr. Allvar Gullstrand (born 1862), professor of ophthalmology in the University of Upsala, Sweden, for his investigations in physiological optics. (2) *Prize for physics:* awarded on November 7 by the Royal Academy of Sciences, Stockholm, to Dr. Willy Wien (born 1864), professor of physics at the University of Würzburg, Bavaria, for his discoveries regarding the laws of radiation. (3) *Prize for chemistry:* awarded on November 7 by the Royal Academy of Sciences, Stockholm, to Mme. Marie Curie (born 1867), professor of physics in the University of Paris (Sorbonne), for her discoveries of the chemical elements radium and polonium, and her investigations regarding their chemical properties. Mme. Curie received, together with her husband, the half of the Nobel prize for physics in 1903 for their investigations regarding the Becquerel rays. (4) *Prize for literature:* awarded on November 9 by the Royal Swedish Academy of Literature, Stockholm, to Maurice Maeterlinck (born 1862). The prize for work in the cause of peace will probably not be awarded before December 10, the day of Dr. A. Nobel's death, by the Storthing (Parliament) in Christiania, Norway.

WE notice with regret the announcement that Dr. R. D. Roberts, Registrar of the Board for the Extension of University Teaching, University of London, and secretary and lecturer to the Gilchrist Educational Trust, died suddenly on November 14, at sixty years of age. Dr. Roberts was widely known and esteemed, and his death will come as a great shock to all those who were brought into association with him. An obituary notice in *The Times* gives the following particulars of his career. He was educated at University College, London, and Clare College, Cambridge, of which he was a foundation scholar and later a fellow. He was also a fellow of University College. His university career was a brilliant one. At University College, where he took the D.Sc. degree in 1878, he carried off the university scholarship in geology, and at Cambridge he took a first class in the natural sciences tripos. In 1879 Dr. Roberts was appointed university lecturer in geology at Cambridge, having previously been an examiner in that subject. Six years later he became secretary to the London Society for the Extension of University Teaching, and afterwards secretary for lectures of the Local Examinations and Lectures Syndicate, Cambridge, before taking up his work at the University of London. The fruits of his wide experience were gathered in his book "Eighteen Years of University Extension," and he also wrote "An Introduction to Modern Geology." As secretary to the Congress of the Universities of the Empire, which is to be held in London next year, his work of organisation has been of great value.

THE Royal Scottish Geographical Society has awarded the gold medal of the society to Mr. J. Y. Buchanan, F.R.S., for his distinguished services to geography, especially in connection with oceanographical research.

MR. R. J. GODLEE has been elected president of the Royal College of Surgeons of England, in succession to Sir Henry Butlin, Bart., who has resigned that office on account of ill-health.

THE Paris correspondent of *The Times* reports that the French Government has conferred upon Halil Bey, director of the Imperial Museum at Constantinople, the rank of Commander in the Legion of Honour, and the rank of Officer upon Prof. Lowell, president of Harvard University.

MR. ARTHUR COOPER, of Middlesbrough, has been elected to succeed the Duke of Devonshire in the presidency of the Iron and Steel Institute next May. Mr. Cooper was awarded the Bessemer gold medal of the institute in 1892 for his services to the metallurgy of iron and steel.

THE Berlin correspondent of *The Times* announces the death, at seventy-four years of age, of Dr. Bernhard Fränkel, who enjoyed a European reputation in his own subject of laryngology, both as a practitioner in Berlin and as the author of many scientific works, and the inventor of improved methods and instruments.

A REUTER message from New York states that Mr. Andrew Carnegie has given the Carnegie Corporation, which was organised on November 10, 5,000,000*l.* in gold bonds of the Steel Corporation. The corporation has been founded for the purpose of the advancement and diffusion of knowledge and understanding in the United States, for the formation of a hero fund, and other purposes.

THE Jean Reynaud prize of ten thousand francs, which is awarded by the Paris Academy of Sciences every five years for the work of an eminent savant, has been awarded this year to Prof. Emile Picard, professor at the Sorbonne and at the Ecole Centrale. Previous awards of the prize have been to MM. Lippmann, Henri Poincaré, and Pierre Curie.

The De Morgan medal of the London Mathematical Society has been awarded to Prof. Horace Lamb, F.R.S., for his researches in mathematical physics. At the annual general meeting of the society, held on November 9, the following were elected to be the council and officers for the session 1911–12:—*President*, Dr. H. F. Baker; *vice-presidents*, Mr. J. E. Campbell and Prof. A. E. H. Love; *treasurer*, Prof. Sir J. Larmor; *secretaries*, Mr. J. H. Grace and Dr. T. J. I'A. Bromwich; *other members of the council*, Mr. G. T. Bennett, Prof. W. Burnside, Mr. E. Cunningham, Mr. A. L. Dixon, Dr. L. N. G. Filon, Mr. J. H. Jeans, Mr. J. E. Littlewood, Prof. H. M. Macdonald, Major P. A. MacMahon, and Mr. A. E. Western.

The disease known as "infantile paralysis" has recently been added to the list of notifiable infectious diseases in London by an order under the Public Health Act. This disease, known medically as acute anterior polio-myelitis, was referred to in our "Notes" columns of October 12 (p. 494), and, though probably not existing in London at the present time, was epidemic in the Plymouth district this summer. In this epidemic, an account of which was given by Dr. Bertram Soltau in *The British Medical Journal* of November 4, 154 cases were notified between May and September, of which 34 died, a case mortality of 22 per cent. The disease may therefore be an important one, and sanitary authorities will do well to be on the look-out for it and to exercise the option they possess of making it notifiable.

The death is announced, at the age of eighty-four, of Mr. Daniel F. Drawbaugh, a veteran American inventor. He was a self-taught man, and worked in his early years as a clockmaker in his native village in Pennsylvania. He became an enthusiast on the subject of physics, and made electrical apparatus a special study. In 1860 he devised an instrument for the electrical transmission of speech, and in 1870 claimed to have invented a magneto-transmitter similar to Bell's. In 1881 his claim to be the inventor of the telephone was adversely decided in the courts, his interests being represented by the People's Telephone Co., against which the Bell Co. brought a suit. Mr. Drawbaugh made only a moderate fortune with his inventions, which included an interchangeable telephone and telegraph apparatus, the collapsible lunch-box, the first nail-making machine, higher grade electrical grain-weighing devices, and various pneumatic tools.

The following announcements have just been made by the Meteorological Office:—Mr. G. I. Taylor, fellow of Trinity College, Cambridge, Smith's prizeman, 1910, has been appointed Schuster reader in dynamical meteorology for three years from January 1, 1912; Mr. L. Southerns, of Emmanuel College, Cambridge, has been appointed special assistant at Eskdale Observatory; Mr. G. Dobson, research student of Gonville and Caius College, Cambridge, has been appointed graduate assistant for research in atmospheric electricity for one year from October 1, 1911. Dr. Arthur Schuster, F.R.S., has presented to the Eskdale Observatory an instrument, made in St. Petersburg from designs by Prince Boris Galitzin, for the registration of the vertical component of seismic movements. Dr. Schuster had previously presented corresponding instruments for registering the horizontal component, so that all three components are now the subject of continuous registration.

The death is announced, in his seventy-first year, of Mr. Holt S. Hallett, who was widely known as an engineer and traveller. From 1860 to 1868 Mr. Hallett assisted in the construction of railways in Lancashire and Cheshire. In 1868 he entered the Indian Public Works Department, and was employed in the construction of the oldest line in Burma, that from Rangoon to Prome, which was completed in 1877. He retired from the public service in 1880, and was soon engaged in the exploration of the little known country between Moulmein and Kiang Hsen on the Mekong for a railway route into Siam, and made a survey for a branch line to Bangkok. He explored about 2500 miles of country, and discovered the sources of the Menam. The general results of his explorations were laid before the Royal Geographical Society in 1883, and an account of his work is to be found in his "A Thousand Miles on an Elephant." He revisited Siam, Burma, and India in 1885, and at the request of the Foreign Office and the War Office sent in a report, with maps, bearing on the political state of affairs in Indo-China. In 1887 Mr. Hallett received the silver medal of the Socity of Arts for a paper on new markets and the extension of railways of India and Burma.

A point which is now agitating the aëronautical industrial world is one that is down for discussion on the agenda of the International Aëronautical Federation, which meets at Turin on November 25. It is, briefly, that it should be made compulsory for aëroplane manufacturers to submit a specimen machine of each type made by them to the representatives of the International Aëronautical Federation, *i.e.* the Aëro Club, in their respective countries in order to receive a certificate of soundness of construction. It will be obvious at once that at the present time such a rule is absurd, for the chief reason that, for instance, in this country only the manufacturers themselves are capable of passing an expert opinion on the merits of any machine submitted. Furthermore, if carried out, it would shift responsibility from the manufacturers to the aëro clubs, which are privately organised bodies, and it would tend to confine the manufacture of machines to certain standard types and close the way to originality and progress. Manufacturers are already up in arms in this country against this extraordinary measure, which, it may be stated, has its origin in France, and it is to be hoped that the delegates of the Royal Aëro Club will receive instructions to oppose it to the utmost. In such attitude they will, no doubt, have the support not only of the club they represent, but also of the German and Italian organisations.

At the meeting of the Concrete Institute held on November 9, Sir Henry Tanner, C.B., delivered his presidential address. During the course of his remarks he said that the membership of the institute is now about 875, and that during the eighteen months ending in June last the net gain was twenty-one. There is no institution, he pointed out, concerned particularly with structural engineering; and the committee of the institute has been empowered to take steps to foster structural engineering, and thus in future the Concrete Institute will be an institution of structural engineers as well. Sir Henry Tanner went on to say that the Institution of Civil Engineers has taken up the subject of reinforced concrete, and a considerable sum of money has been devoted to experiments which are in process of being carried out. There is no doubt, he said, that experiments are needed in this country to obtain a consistent and complete series based on materials to be obtained here and mixed and tested under similar conditions. At the present time we have to rely on experiments in America, Germany, and France with cement of varying character, and it would be of the greatest advantage if these could be repeated in some cases at intervals, the improvement in strength being so great for

some years. Later in the address he referred to the committee appointed by the Board of Education to inquire into the question of economy in building, and as to whether buildings of a more temporary nature could not be brought into use. Reinforced concrete came in for its share of the discussion by the committee; but the estimates of cost varied largely, from 33 per cent. less to 10 per cent. more than for ordinary building. No difference of locality will account for these variations. Witnesses having a more intimate knowledge of the cost of such buildings might have been called. It is little good encouraging specific proposals for the use of novel materials while local by-laws make no provision proper to the use of reinforced concrete. In order, however, to remove this difficulty, it has been suggested that legislation should be promoted to exempt school buildings, the plans of which had been approved by the Board of Education, from the operation of local building by-laws.

A PAPER on a novel and important subject appears in *The Naturalist* for November. The writer, the Rev. Hilderic Friend, has brought together some interesting facts relating to *Octolasium gracile*, Oerley, which is usually found very sparsely, but at Sutton Broad is the dominant Allolobophora; and *Aporrectodea similis*, Friend, a species which is at present known only from the Kew Gardens. An account of the species of Fridericia found at the Eel Hut, where the River Ant enters the Barton Broad, is also very suggestive. Out of twenty-four Euchytræids, belonging to six different species, twenty-two were Fridericias, belonging to five species, of which two have not been observed hitherto in England. One question to be solved is, Does each species do the same work as all the rest, or does one prepare the way for the others?

MR. O. A. RHOUSOPOULOS contributes to vol. ii., No. 5, of *The Museums Journal* an important article on the methods of cleaning and preserving antiquities. The most frequently recurring objects which need preservation are those of copper or copper alloys. For these various methods are considered: soaking in distilled water; saturation with paraffin; reduction treatment by heating in a current of hydrogen, by an electric current in a bath of potassium cyanide or caustic soda. Some of the above methods, which in their present perfection leave little to be desired, may be applied to gold, silver, and their alloys; but the use of a solution of potassium cyanide yields better and more rapid results. Wood and fibres are soaked with antiseptic solutions, and finally receive a coating of celluloid varnish. The article ends with many valuable suggestions for the treatment of objects of iron, lecythi and other coloured earthenware, marble, and porous limestone. The instructions throughout are practical and detailed, and the article may be commended to the attention of all curators of museums.

THE Sutton Broad Biological Laboratory, started in 1902 by Sir Eustace Gurney, and, we believe, still the only fresh-water biological laboratory in this country, has so far well justified its existence. In the current number of the Transactions of the Norfolk and Norwich Naturalists' Society are two papers, emanating from this laboratory, which are of especial interest with reference to the much debated question as to what constitutes "tide" on the Norfolk Broads. For several years past observations, made with a portable recording tide-gauge, have been kept at the laboratory by Mr. Robert Gurney; and in the publication referred to these have been incorporated into a paper, well illustrated with charts. In the same journal Mr. A. G. Innes contributes a paper on the distribution of salt in the River Bure and its tributaries; and, taken together, these two papers are a valuable addition to our knowledge on the subject.

THE report of the Northumberland Sea Fisheries Committee on the scientific investigations conducted under its auspices during the year 1910 and up to June 15, 1911, has now appeared under the editorship of Prof. Alexander Meek, of the Armstrong College, Newcastle-upon-Tyne. It includes some interesting observations on mesmerising lobsters and other crustaceans. It is known that a lobster may be put into a comatose condition by rubbing it along the back of the carapace. The usual way is to hold the lobster head down, with the claws arranged so as to form a support with the rostrum, and to stroke it rapidly with the tips of the fingers. In about a minute the lobster succumbs, and remains without movement in this position for a variable period. With a view to see whether the reversed position, as determining the blood to the head, was essential, a lobster was treated in the horizontal attitude, and so successfully that it remained without movement for three hours. A Norway lobster subjected to a similar treatment was quiescent for fifty-five minutes. A lobster can be put to sleep on its back. The crab goes to sleep usually in the tucked-up condition—and may be left in the natural position or on its back. They all recover when disturbed; but the recovery of the lobster appears to be quicker if the undersurface of the cephalo-thorax is disturbed. Placed in sea water lobsters recover immediately, but in one such case a crab took ten minutes to come round completely. During the sleep the scaphognathite is in action all the time.

MR. E. J. SHEPPARD contributes to the Journal of the Royal Microscopical Society for October observations on the reappearance of the nucleolus in mitosis. He finds that, in the dividing cells of hyacinth and other plants, there appear, at the close of the diaster stage, one or more loops of chromatin in each future daughter nucleus. At a little later stage, when the division of the cell is well marked, the nucleolus makes its appearance, apparently by a streaming, into the area enclosed by the loop, of material from the chromatin. Mr. Sheppard has not been able to trace corresponding changes in the loop-areas of animal cells. He regards the nucleolus as inciting or stimulating the process of mitosis.

DEALING with the subject of alpine gardens in a lecture published in the Journal of the Royal Horticultural Society (vol. xxxvii., part i.), the Swiss botanist M. H. Correvon states that the English climate suits alpine plants better than the continental climate in Switzerland, except such tufted dwarf plants as the species of Eritrichium and Androsace. This statement follows upon a description of the chief features observed in the gardens at Friar Park, Leonardslee, and other notable alpine gardens in Great Britain. Reference is made to the interesting Swiss garden of the Linnaea at Bourg-St.-Pierre in the Valais, where the choicest developments are the masses of *Papaver alpinum*, superb growths of *Eryngium alpinum*, *Heuchera sanguinea*, and *Epilobium latifolium* and abundance of edelweiss. M. Correvon claims for his countrymen the superiority in plant culture on walls, where saxifrages, androsaces, campanulas, and other suitable plants can be induced to make a brilliant show; he also mentions that the walls bordering the mountain railways from Territet to Glyon and Vevey to Pèlerin have been so planted.

IN *The Agricultural Journal of India*, part iii., Mr. Keatinge continues his account of the rural economy of the Bombay Deccan, dealing specially with the livestock.

Great improvements seem to be possible. Ponies, which once had a high reputation, are now poor; goats and sheep do not bring in anything like the profit they might; whilst the cattle also appear to have deteriorated during the past fifty years. These changes are largely attributed to the large increase in cultivated ground and the consequent reduction in the grazing area. An interesting account of grape-growing round Peshawar, accompanied by some good illustrations, is given by Mr. Robertson-Brown.

THE cultivation of cacao is a highly important industry in Trinidad, where also the great bulk of the planters are peasant proprietors. Hence the problem before the staff of the Department of Agriculture is of a dual nature; new methods have to be worked out for improving yields and coping with pests, and these methods have to be brought to the notice of the grower. In a batch of circulars recently to hand instructions are given in the methods of cultivation calculated best to suit a small proprietor. The entomological and mycological notes by Messrs. Guppy and Urich will be found of more general interest. It is stated that leaf-eating beetles were very common last year, particularly *Neobrotica colaspis*; pod-hunters (*Horiola arcuata*) have also been locally numerous.

IN Bulletin No. 7 of the Commonwealth Bureau of Meteorology the climate of the proposed Federal Capital Territory at Yass-Canberra, in New South Wales, is dealt with. Besides a few preliminary paragraphs, the whole Bulletin is devoted to tables of the mean monthly values for twelve stations, and the average maximum and mean rainfall for a considerably larger number. Rainfall and temperature data are also shown for an area of about eight square degrees on a map, which might conveniently have been on a smaller scale, the isotherms being drawn in by interpolation from the twelve observing stations and by employing corrections of 1° F. for each 300 feet of altitude and each degree of latitude. No. 8 Bulletin of the same Bureau deals with the physiography of the same area. Mr. G. Taylor treats by the modern explanatory method the land-forms for a radius of about 20 miles round Canberra. Various parts are first described in their present condition, after which the past development of the region is worked out. An ancient peneplain was uplifted for some 800 feet and then maturely eroded, after which a period of unrest set in, during which blocks have been tilted, and the drainage system thereby considerably modified, numerous cases of river-capture occurring. The report is illustrated by sketch-maps and diagrams, and gives a good idea of the area, which would have been improved by a short general description of the main features of this part of New South Wales.

IN Heft No. 9 of the *Mitteilungen der k.k. Geographischen Gesellschaft* of Vienna an account is given of the May cruise of the surveying ship *Najade*. Soundings were taken on the line Brindisi-Durazzo, and the considerable depths which observations in 1877 had indicated were not borne out. In lat. 41° 15′ N. and long. 18° 15′ previous soundings of 1500 and 1600 metres are replaced by more correct values of from 1000 to 1100 metres. The greatest depth of the Adriatic, hitherto given as 1645 metres, is now to be taken as 1132 metres somewhat to the north of the point previously indicated in the basin between Novi and Cattaro or Ragusa. A brief summary of the biological work is also given.

IN the November number of *The Geographical Journal* there appears a map of Africa on which are shown in different grades of colour the portions systematically surveyed, those mapped by good route traverses, and the areas which are but roughly mapped or known only by report. While the second class covers a large area, systematic survey is limited to frontier lines and to areas in Algeria, Egypt, Uganda, South Africa, and a few other points. There still remain vast areas both for exploration in its true sense and for systematic study, and if a corresponding map had been prepared to show our knowledge of the continent from other points of view than its topography the scope for investigation would be seen to be even wider than appears from the present map.

IN the *Zeitschrift der Gesellschaft für Erdkunde* (No. 7) Prof. K. Kretschner completes his survey of the manuscript maps of the National Library at Paris. These date mostly from the sixteenth and seventeenth centuries, and are of the class known as compass charts or portolan maps. While some bear the name of the author, many are anonymous; and maps of both classes are described in the present article, which deals only with those hitherto unknown or which have been very imperfectly treated. The investigation was undertaken in order to improve our knowledge of this portion of early cartography by examining, so far as possible, all the maps preserved in different countries or cities, as has been very completely done for Italy and largely carried out in Germany.

THE October number of *Le Radium* contains a short note by Madame Curie on the variation with time of the activity of some radio-active substances. The measurements have extended over several years, and the results given have been standardised by the use of the piezo-electric charge on quartz. The black oxide of uranium tested for four years in an ionisation chamber in which the whole of the α radiation was absorbed showed no change. Actinium showed a decrease of activity of about 10 per cent. in three years; and Madame Curie assigns to it a mean life of thirty years. Radium, purified from emanation and from traces of radium D, E, and F, was tested by means of its β and γ radiation, and found to increase in activity 5 per cent. in two years. Madame Curie attributes this increase to the formation of radium E. Radium D, purified from radium E and F, appears to have a life of about twenty-five years. The measurements are being continued so that the changes observed in succeeding years may be determined.

IN the July number of the Tokio *Sugaku-Buturigakkwai Kizi* Mr. S. Nakamura describes a panoramic camera by means of which the whole horizon (360°) can be photographed on a stationary film, which is bent into a cylinder and suitably supported inside the camera wall. In order to get the image on the film it is necessary to have two reflecting surfaces parallel to each other and inclined at an angle of 45° with the vertical axis of the camera, the one above the camera to receive the light from the view, and the other within to receive it from the upper mirror and reflect it to the film. The lens may be horizontally in front of either of the reflectors or vertically between them, and in making an exposure the complete optical system revolves on its vertical axis. The chief optical condition necessary in all such apparatus is that the second nodal point of the objective must be at the centre of rotation, and in this case in the centre of the camera. With ordinary photographic objectives, in which the nodal points lie within the objective itself, it is difficult, if not impossible, to fulfil this condition in these circumstances. The author therefore uses a lens which consists of a negative as well as a positive combination, as in telephotographic lenses, so that the nodal points are thrown well outside the objective; it is then only a matter of construction to fulfil every necessary

condition. The camera may be compared to a large pill-box, but the lid, which carries the rotating optical system, is as deep as the box within which the film is held by two rings, one notched or marked to indicate on the photograph the azimuths of the objects on the picture. A right-angled prism is preferred for the upper reflector, and the rotation is done by hand by means of a toothed wheel and endless screw.

THE first annual report of the Road Board, established under the powers of the Finance Act of 1909, has been recently published. This Board was formed for the purpose of improving the main roads of this country, rendered necessary by the general adoption of motor vehicles. The funds required for the purposes of the Board are derived from the duties imposed on motor spirit and motor licences levied under the powers of the Act. The applications for aid from local authorities amounted to 7,870,459*l*. Up to the end of June the Board had been able to allocate out of the money placed at its disposal for the first year, 1,161,000*l*., the sum of 270,824*l*. This sum was to be applied to the improvement of main roads and important connecting roads passing through rural areas; also to the improvement of the surface of the roads and the alleviation of the nuisance arising from mud and dust due to motor traffic, and to bringing the road surfaces up to such a standard of construction that the cost of future upkeep to the local authorities may be brought within the means available from local sources. For this purpose the Board has sanctioned the use of bituminous binding material, and has issued general directions and specifications relating to the treatment of road surfaces. The Board has also taken steps to establish at the National Physical Laboratory at Teddington a laboratory for testing the value of different kinds of stone used for road repairs. This work is to be under the direction of the Geological Survey.

A CATALOGUE of gardening books and literature, comprising many early works, has been issued by Messrs. John Wheldon and Co., Great Queen Street, London. The items are arranged under the sections of flower, fruit, kitchen and landscape gardening, trees, conservatory and general treatises.

IN the notice of those volumes of "The Home University Library" published in NATURE of November 9, it was stated that "ten volumes will be issued each year." The publishers, Messrs. Williams and Norgate, ask us to say that the plan of publication is to publish ten volumes in each set at intervals of three or four months. Since April last thirty volumes have been issued, and at least one hundred are planned.

Forthcoming Scientific Books.—In the "Fauna of British India" Series, Canon W. W. Fowler's volume on the Cicindelidæ and Paussidæ, with a general introduction to the Coleoptera, and Mr. E. Brunetti's work on the Nemocera (excluding the Chironomidæ and the Culicidæ), are in the press. The remaining volumes which the editor, Mr. A. E. Shipley, with the assistance of Mr. Guy A. K. Marshall, and with the sanction of the Secretary of State for India, has arranged for in this series are:—volumes on the Orthoptera (Acridiidæ and Locustidæ), by Mr. W. F. Kirby; on butterflies (Lycænidæ and Hesperiidæ), by Mr. H. H. Druce; on the Curculionidæ, by Mr. G. A. K. Marshall; on the Ichneumonidæ, by Mr. Claude Morley; on the longicorn beetles, by Mr. C. J. Gahan; on the Blattidæ, by Mr. R. Shelford; on the Helicidæ, by Lieut.-Colonel H. H. Godwin-Austen; on the Ixodidæ and Argasidæ, by Mr. C. Warburton; on leeches, by Mr. W. A. Harding; on the Meloidæ, by Prof. Creighton Wellman; on the brachyurous Crustacea, by Lieut.-Colonel A. Alcock; and on the Unionidæ, by Mr. H. B. Preston.—Mr. Edward Stanford, official agent for the large-scale Ordnance maps, announces the publication of the first 165 sheets of a new issue on the scale of 50 inches to a mile (1 : 1250). Hitherto, apart from the town plans, the largest scale on which urban districts have been obtainable has been the well-known 25 inches to a mile, and the new issue is based on an enlargement of that map. The larger scale map has been specially prepared for use primarily in connection with land valuation, and the area covered by each sheet is one quarter of that of a 25-inch sheet.—The eighth edition of Fream's "Elements of Agriculture" is to be published by Mr. John Murray. The work of editing has been entrusted to Prof. J. R. Ainsworth Davis, of the Royal Agricultural College, Cirencester, who has considerably extended the scope of the book and brought it up to date.

OUR ASTRONOMICAL COLUMN.

PLANET MT.—The new and interesting minor planet discovered by Dr. Palisa on October 3 has, apparently, been lost again. It will be remembered that Dr. Palisa made observations on October 3 and 4, and Herr Pechüle on the latter date; but bad skies interfered and further observations were prevented. Then the Greenwich observers took a plate on October 25, with the Franklin-Adams camera, which showed apparent images in the supposed position of the planet. However, good plates taken the next night did not confirm this, and there is little doubt that the supposed images are spurious. This is most disappointing, for, as Dr. Crommelin points out in No. 441 of *The Observatory*, the object promised to be of extraordinary interest. The present known data are insufficient for a determination of the orbit, but the observations could be satisfied by assuming an orbit having about the same perihelion distance as Eros, with a slightly greater eccentricity. To explain its apparent disappearance, Dr. Crommelin suggests that, like Eros at some oppositions, this object may be rapidly variable in apparent brightness. Its motion showed it to be very near to the earth, and there is no need to suppose its diameter to be greater than a mile or two. Such small bodies need not be spherical; in fact, they might be discoidal, and would, therefore, suffer considerable changes of apparent brightness. The suggestion that Dr. Palisa's object might be a non-nebulous comet, such as Kopff's, moving in a parabolic orbit, is discounted by its planetary aspect and by the fact that an ellipse would fit the observations.

MARS.—Writing from the Sétif Observatory on November 4, M. Jarry-Desloges announces the appearance of seven fissures, towards M. Acidalium, in the north polar cap of Mars, and states that a bright area was seen on Nerigos.

From the Massegros Observatory, on October 31, it is reported that Juventæ Fons was easily visible, and that Coprates was dull and appeared bifurcated near L. Tithonius; three "lakes" were seen on Coprates, and several small ones on the site of Araxes. The south polar spot is said to be very luminous (*Astronomische Nachrichten*, No. 4534).

EPHEMERIDES FOR VARIOUS COMETS.—Nos. 4533–4 of the *Astronomische Nachrichten* contain ephemerides for Borrelly's (1911*e*), Brooks's (1911*c*), Quénisset's (1911*f*), and Beljawsky's (1911*g*) comets. Borrelly's comet is now just below τ^3 and τ^4 Eridani, and is moving northward at a little more than half a degree per day; it is of about magnitude 13·0. Brooks's comet is now travelling southward through Virgo at nearly a degree a day, and will be near γ Hydræ on November 21; its calculated magnitude now is about 4·5, and it is unlikely to be observed further in these latitudes. Observers in the southern hemisphere should, however, be able to follow it for some time yet.

Quénisset's comet is now near the sun, and practically unobservable; its calculated magnitude is about 7·0, and,

travelling southward, it is about half-way between μ and ϵ Serpentis.

Beljawsky's comet is now fainter than the sixth magnitude, according to the ephemeris, and is three or four degrees north-east of Antares; it is practically unobservable, and is apparently travelling southwards, while receding from both the sun and the earth.

THE DISTORTION AND APPARENT DILATATION OF CELESTIAL OBJECTS AT THE HORIZON.—Mdlle. G. Renaudot has an interesting article on this subject in No. 2002 of *La Nature*, where she discusses the numerous explanations which have been put forward since the time of Aristotle. Special attention is paid to the explanation suggested by Alhazen, which calls in an optical flattening of the celestial vault causing the observer to feel that the stars, &c., are nearer to him, *i.e.* they should subtend a greater angle than they really appear to do. The interest of the article is greatly enhanced by some excellent photographs, taken by M. Quénisset, illustrating the distortion of the solar disc near the horizon.

EARLY VISIBILITY OF THE NEW MOON.—Referring again to Mr. Horner's observation of the new moon, Mr. Whitmell, in *The Observatory*, makes one or two minor additions to his previous results, and quotes another case, more remarkable still, inasmuch as the moon's age was only 14·75 hours, which has been brought to his notice. Mr. Hoare, of Faversham, sweeping the horizon with a 4-inch refractor on July 22, 1895, picked up the crescent moon, and after steady gazing was able to hold it with the naked eye. In this case the difference of altitude between the sun and moon was 4° 28′, the former being 2° 19′ below, the latter 2° 7′ above, the horizon, and the difference in azimuth was 7° 5′.

A NEW ASTRONOMICAL SOCIETY AND PUBLICATION.—We have received one or two numbers of the *Revista de la Sociedad Astronómica de España*, the monthly illustrated publication of this newly formed society. The review is well printed on good paper, and, in addition to the notices of the society, ephemerides and phenomena for the month, &c., it contains some excellent illustrated articles.

SOME PAPERS ON SPIDERS AND INSECTS.

TO the Proceedings of the Academy of Natural Sciences of Philadelphia for May Mr. N. E. M'Indoo contributes an article on the lyriform organs and tactile hairs of spiders. The lyriform organs, first observed in 1878, are sensory skin-structures peculiar to arachnids, and consist usually of several more or less nearly parallel slits, generally surrounded by a dark lyre-shaped band. In the simple type there are only two or three slits, with a common border; but in the compound type there are from four to thirty slits, all of which may be enclosed in a common border, or each of which may have a border of its own. The lyriform organs attain their greatest complexity in the hunting-spiders, "and as these usually contain more slits than those of the snarers or tube-dwellers, we must conclude that the method of capturing food has brought about these changes in the number of organs." As regards their precise function, the author is convinced that these organs have nothing to do with the sense of hearing, which appears to be undeveloped among spiders.

Owing to the rapid development and opening up of the country, and the consequent introduction of enormous quantities of seedlings, shrubs, trees, &c., Canada is specially liable to suffer from the accidental introduction of noxious insects. Accordingly, in May, 1910, the Dominion Parliament passed "an Act to prevent the introduction or spreading of insects, pests, and diseases destructive to vegetation." A copy of this Act is published as Bulletin No. 1 of the Entomological Division of the Canadian Department of Agriculture.

Among destructive insects that have reached Canada from Europe, two of the worst are the spruce budworm (*Tortrix fumiferana*) and the larch saw-fly, the ravages of which, coupled with those of other insects, to forests are estimated in a pamphlet by Dr. C. G. Hewitt, the Dominion entomologist, issued by the British Whig Publishing Company, Kingston, Ontario, to be as serious as the losses due to forest fires. Both insects are now spread over large areas in eastern Canada. The former species, which was first observed in force in 1909, defoliates balsam and spruce, and is reported to be doing the same to Douglas pine in British Columbia. Spreading like fire, in the adult stage this insect extends its range in a manner which cannot be controlled by ordinary means. The larch saw-fly, which thrives as well on the American larch as on its European namesake, was first observed in America in 1881, and two years later had spread over the New England States, whence it made its way into Canada by 1882. It attained a great development between that year and 1885, but after that practically disappeared until 1904, when it once more began to increase; at the present time it is spread over an area of 2500 miles. The best hopes of keeping the insect in check are centred on on ichneumon fly (*Mesoleius aulicus*), which appears to have been introduced for this purpose, although it is not quite clear whether the author is referring to its work in England or Canada.

In the September number of *The Entomologist's Monthly Magazine* Messrs. Porritt and Bankes give notes, illustrated by a coloured plate, of nine interesting species of British insects. Among these is the moth *Nonagria neurica*, taken for the first time in this country in the Cuckmere Valley, Sussex, in 1908, the British specimens hitherto referred to this species being shown to belong to an allied form. The caterpillar and pupa are described by Mr. H. M. Edelsten in a separate paper, also illustrated by a plate.

A list of the Macro-Lepidoptera of the Falmouth district, by Mr. W. A. Rollason, is published in the seventy-eighth annual report of the Royal Cornwall Polytechnic Society.

SEISMOLOGICAL NOTES.

IN the *Bulletin de l'Académie Impériale des Sciences de St. Petersbourg*, VI Série, October 1, Prince B. Galitzin adds another valuable contribution to seismometry. In No. 14, 1909, of the same Bulletin he pointed out that the azimuth of an earthquake epicentre can be determined from observations made at a single station. This direction is that of the first longitudinal wave, and is obtained by taking the resultant of amplitudes recorded in two directions at right angles to each other. Because horizontal pendulums are usually oriented north-south and east-west, the displacements are given in these directions. If, for example, one instrument recorded 10 mm. of north-south motion and the other 10 mm. of east-west motion, we see that the direction of motion was N.E.-S.W., but we do not know if it came from the north-east or from the south-west. This is the question that Prince Galitzin answers. If the front of the first wave is dilatational in character this motion is towards and down to the epicentre, but if it is condensational it is away and up from the same. This distinction is made clear by the records of a seismograph recording vertical motion. Observations have shown that sometimes the first movement of this instrument is upwards and sometimes it is downwards. The upward motion indicates a condensation, and the latter a dilatation. Between July 2, 1909, and June 8, 1911, Prince Galitzin has determined the position of forty-two epicentres by methods in which these rules have been followed.

In the issue of the same Bulletin for October 15 we find two more instructive communications from Prince Galitzin. The first deals with observations on the vertical component of earthquake motion. In connection with this, one result, based upon the records of six large earthquakes, is that the ratio of the vertical and horizontal components of movement is not constant, and is less than that which might be expected. Another result is based upon the apparent angle of emergence. Observations of nineteen earthquakes show that those with origins at distances varying between 2260 and 3840 km. have given values for these angles decreasing from 51 degrees to 42 degrees. From this latter distance up to 14,600 km. the values have increased up to 76 degrees. No definite law for the relationship between distance and the angle of emergence can yet be formulated. The second communication, which was brought before the Academy on September 21, deals

with the direction of motion of the second or transversal phase of earthquake movement. So far as observations have gone, the inclination of the plane of this movement with the plane passing through the epicentre, an observing station and the centre of the world has wide limits. Its value is probably influenced by the geological character of strata in the neighbourhood of the observing station and the epicentre. These investigations, which are treated from the mathematical and observational sides, are well worthy of attention from all seismologists.

Another interesting note we find in *Rendiconti della R. Accademia dei Lincei*, vol. xx., serie 5ª, 2nd sem., fasc. 1°. This is a short paper on the Latium earthquake of April 10, by Dr. G. Agamennone. The commencement of this disturbance was noted at Rocca di Papa at 10h. 43m. 39s., with a strong reinforcement one second later. At Rome the corresponding times were 10h. 43m. 41s. and 10h. 43m. 44s. These times indicate that the epicentre is nearer to Rocca di Papa than it is to Rome. If it is assumed that the records at each of these places refer to P_1 and P_2, tables like those of Zeissig give a distance of the epicentre from each of these stations. These distances are respectively 10 and 30 km. But as circles with these radii intersect at two points, we are left to choose between two epicentres, and as neither of these falls in with local observations, in this instance, at least, this method of determining origins is found insufficient. To solve the difficulty, Dr. Agamennone shows that the ratio of the differences in time of arrival of the two phases of motion at the two given stations, which we will call A and B, which is a constant, can be expressed in terms of the coordinates of the epicentre x and y and the distance between A and B. To solve this equation with two unknowns three assumptions are made, one, for example, being that the epicentre lies on AB, with the result that three solutions are obtained. The one selected is that which agrees best with local observations. The method is new, but it is hardly applicable to time observations made at only two stations.

EDUCATIONAL SCIENCE AT THE BRITISH ASSOCIATION.

BISHOP WELLDON'S presidential address has already been printed in NATURE, and it is therefore unnecessary to dwell upon it at any length. Teachers will find it animated by a high conception of the dignity and influence of their calling and a sympathetic insight into its characteristic difficulties, as might be expected from a one-time headmaster of a great English public school, though they may consider it lacking in practical suggestion for raising the profession in the general estimation, the public-school headmaster, happily for himself, being exempt from the necessity for considering such mundane matters as tenure, salaries, and pensions. To the general reader the most interesting part of the address will probably be Dr. Welldon's remarks on the relations of the Board of Education with the secondary schools and with the local authorities, which were prompted by his experience as deputy chairman of the Manchester Education Committee. He has learnt that the antagonism between the schools and the rates is a constant quantity, and that, accordingly, new services imposed on the authorities, commendable in themselves, as, for instance, the feeding of necessitous children and medical inspection, will in part be paid for out of funds which are needed for the performance of the older duties, unless, indeed, the Board of Education can induce the Treasury to grant additional help from public funds, a consummation which is likely to remain unrealised so long as the Parliamentary chiefs of the Board are chosen from ex-Treasury officials. In the Board's relations with the schools Dr. Welldon deprecated the tendency to a bureaucratic regulation of details, which is well known to characterise the dealings of the Board with elementary schools. Such methods may be wholesome when applied to unsatisfactory schools, for they assure a minimum of efficiency; but the maximum of efficiency cannot be obtained under a code of regulations—it requires freedom, spontaneity, and individualism for its growth.

The reference to educational topics, which has almost become customary in the presidential addresses to the whole association, was this year concerned with the position of technical education. Sir William Ramsay urged the need for the concentration of higher technical instruction in a few important institutions in place of its dispersal, as at present, through the many struggling technical institutes which have been established up and down the land by the local authorities. In one of the sectional discussions Prof. R. A. Gregory roundly stated that the position of higher technical instruction in England was in a deplorable condition. Official statistics showed, he said, that fewer than 2000 students were taking complete day courses in the whole of the technical institutes of the country.

The initial discussion in the section took place upon the report of the committee on overlapping between secondary schools and universities and other places of higher education. Prof. Smithells, in presenting the report, made it clear that it dealt only with a certain amount of evidence—in some cases conflicting evidence—and that its conclusions must be reserved for a later meeting. The complaint is made in England, and also in America, that the secondary-school course is not properly articulated with the university course, and that on one side the schools are retaining pupils who ought to be at the universities, whilst on the other the universities, owing to the lack of preparation of many of their students, are wasting power upon elementary training. Upon the evidence submitted, and apart from theories as to the position of pass Moderations and the Previous examination in an organised educational course, Oxford and Cambridge appear to have little complaint to make. At London and in some of the provincial universities the overlapping is more serious. The London external system renders it possible for students to pass their Intermediate examination, and even to take their degree, direct from school, while, on the other hand, a large amount of preparation for matriculation takes place in the London colleges. It must be remembered, however, that many of the students enter the university by way of evening classes or even after a short experience of business or professional life, and for these preparatory work must certainly form part of the university course. The overlapping at London is considerable, but to some extent it cannot be avoided; and, as was suggested in the discussion both by Prof. Smithells and by Mr. Daniell, overlapping in the special circumstances of London and of the larger provincial universities is by no means synonymous with waste of educational resources.

As between the technical institutions and secondary schools, no evidence is yet forthcoming to show that the overlapping is serious. Indeed, the facts appear to be the other way. Less than one-fifth of the students in English institutions have passed a university matriculation examination or its equivalent, and nearly one-fourth have been admitted without passing any examination test whatever. The secondary schools and the technical institutions are thus shown to have but little organic connection, and the great bulk of the students of the latter have probably received no secondary education at all. It will be time enough to discuss overlapping when the main stream of pupils in the higher technical institutions have previously laid the foundation of a good general education in the secondary schools, a condition of things, however, which is not likely to be facilitated by the drastic proposal of one speaker that boys should not be allowed to remain at the secondary schools after their sixteenth year, but should be passed straight on to the technical institutes. The evidence from the secondary schools is still incomplete. As might be expected, the public-school masters with one accord proclaim the advantage to be gained by their boys in the last year or two years of school life. In these years they learn self-control, the use of authority, and the most valuable parts of character training; and the schools, with their ample resources, find no difficulty in allowing their boys a reasonable amount of specialisation in the subjects which they will afterwards study at the universities, and in preparing them for the transition in method between school and college.

For the present, and until the committee reports its reasoned conclusions, it may be taken that in the gaps between the different parts of our educational system the

real danger lies, and that, as for overlapping, in Principal Griffiths's words, "Time is not lost when the same country is retraversed under a different guide."

The principal item on the programme on the second day of the meeting was a discussion on the place of examinations in education, opened by Mr. P. J. Hartog and Miss Burstall. The papers, and the discussion which followed them, may well be taken as marking a new stage in the treatment of the subject. Hitherto there has been more than a disposition on the part of educationists to anathematise all external examinations. As Mr. Hartog indicated, little good has come of it: the external examining bodies are not one penny the worse. It is now realised that for some purposes, as, for example, the selection of candidates for the State service and the certification of professional skill, the public have a right to demand an examination by some independent body. Sir William Ramsay, who intervened early in the discussion, and was by far the most outspoken opponent of the conventional type of examination, at least agreed that "we must be guarded against professional murder." The problem is thus seen to be, not the abolition of examinations, but their reform, and to this end the section strongly supported Mr. Hartog's suggestion that the time is ripe for a Royal Commission to inquire into the whole subject, but with particular reference to the entry into the Civil Service. All the speakers were agreed that teachers should increasingly cooperate in the "branding of their own herrings." Miss Burstall showed how influential the teacher members had been on the Joint Matriculation Board of the northern universities, not as examiners, but as members equally responsible with their colleagues for the scope and arrangement of the examinations. There are other instances in which the cooperation of teachers has been carried very far, and the committee which was appointed as the result of the discussion might very well devote its time to the preparation of a detailed account of some of these experiments and to a report upon the degree of success which has attended them.

Another aspect of the subject was raised by Mr. Hartog and the president of the section in their remarks upon the suitability of many of the examinations for the purpose they have to serve. It is almost impossible by examination to test the *moral* of the candidate; and there are many gifts of tact, alertness, resourcefulness, and the like required in the State service and in professional life which the present system of examinations completely passes by. Mr. Hartog gave an interesting account of a written test which he had himself applied to a group of candidates to ascertain in what degree they possessed certain of these qualities; but such tests are difficult to devise, and—*sub rosa*, be it said—they demand corresponding qualities in the examiners. Dr. T. P. Nunn was for once *advocatus diaboli*, and gave a thoughtful restatement of the arguments for external examinations which satisfied the generation that founded the University Locals. In essence it was the case for the influence of a master in a subject exerted upon teachers and upon the study of it generally through the annual paper of questions. But even in Dr. Nunn's hands it failed to carry conviction; the general level of teaching in schools is much higher in all subjects than it was in days gone by; an increasing number of teachers come under the personal influence of one or other of the masters of their subject; and among those who do not, the professional periodicals and the numerous associations and conferences which are so marked a feature of educational life in this generation supply opportunities for the spread of right method and sound doctrine superior to any that a mere paper of questions can afford.

It is the practice of the sectional committee to set apart one day for the discussion of recent psycho-physical research as connected with education. This year the central topic was that of defective children. A special committee, of which Prof. J. A. Green is secretary, reported the result of an inquiry into the tests actually used in the diagnosis of feeble-mindedness. The summarised replies received from school medical officers and others show that there is a grave need for some standardisation upon scientific lines in the matter both of diagnosis and subsequent treatment. Dr. Shrubsall gave a detailed account of the methods employed under the London Education Authority for the testing of mental deficiency. Without presuming to criticise these methods in particular, it is very clear that the methods of diagnosis generally employed are frankly empirical and of almost bewildering variety, and that partly in consequence of this and partly owing to the lack of precise knowledge on types of mental deficiency in relation to the general problems of education there is very little connection in most cases between the initial diagnosis and the subsequent treatment.

Dr. A. F. Tredgold presented a careful discussion on the nature of mental defect and its relation to the normal. He suggested that neither from the intellectual point of view nor as a result of psychological analysis or histological examination of brain structure could justification be found for regarding the difference between the normal and the defective as in its essence qualitative, although the quantitative differences may and do result in minds of a very different order. In defining mental defect it was necessary to go much deeper than mere ability to perform certain occupations. He would himself define it as a condition due to arrested or imperfect brain development, in consequence of which the individual is incapable of maintaining an independent existence. Dr. Abelson followed with a description of a series of tests, in some measure comparable with Binet's, which he had employed for the last three years upon backward children. The problem of the mentally deficient is so pressing from the social point of view that it is not surprising that the discussion soon turned rather upon this aspect of the question than upon the report of the committee. Once defective always defective, appears to be the rule. "I have never yet," said Dr. Tredgold, "seen a mentally defective converted into a normal being"; and again, Miss Dendy: "We cannot train the defective child out of his defect; he simply grows into a trained feeble-minded man."

The absolute necessity, in the interests of society, of preventing the multiplication of the unfit, and the inefficacy of the present law, which allows the feeble-minded adolescent at sixteen years of age to go out into the world, none saying him "Nay," dominated the mind of speaker after speaker. Dr. Saleeby, Mrs. Burgwin, Prof. Dendy, and Mr. McLeod Yearsley took part in the discussion. The last named urged especially the importance of segregating the feeble-minded deaf. Miss Dendy showed how much can be accomplished even under present conditions in her description of the feeble-minded colony at Sandlebridge, which, beginning ten years ago as a small residential special school for little children, and resolutely declining to accept any new pupil over thirteen years of age, has grown into a colony with 270 inhabitants, with two farmhouses, with cottages, a laundry, carpenters' and plumbers' shops, and six residential houses, on about 120 acres of land. In the ten years, out of 274 children who have been admitted, only eighteen can be spoken of as failures whose parents have broken their promise to leave them permanently in the school. Very interesting was Miss Dendy's account of how it had been possible to turn to the service of the community those streaks and patches of intelligence which are found in almost all feeble-minded children, and, unfortunately, are often made the basis of a training in tricks which are of no use either to the individual trained or to anyone else.

On the last day of the meeting papers were read on practical education in H.M. dockyard and naval schools, by Mr. Dawe, headmaster of the Dockyard School at Portsmouth, and Mr. W. H. T. Pain, principal instructor of boy artificers on H.M.S. *Fisgard*. The *Fisgard* is quite a recent establishment, but the Dockyard School in one form or another has existed for nearly a hundred years. It was claimed by its supporters in the discussion, among them Sir William White, a former pupil in a dockyard school, Profs. Worthington and Gregory, Dr. Kimmins, and Dr. Varley, that the schools might well be taken as a model by authorities responsible for any form of specialised technical training. Of their success there can be no question. Every professor of naval architecture in the kingdom at the present time has been through one of H.M. dockyard schools; of the principal officers in the constructional branch of his Majesty's Navy the same may be said, and also of the majority of naval architects at the head of private shipbuilding firms, while the lower ranks

of his Majesty's dockyards are mainly staffed by ex-pupils. The outlay for which this wonderful return is obtained does not exceed 4000*l*. per annum.

From the beginning the Admiralty has insisted on the faithful observance of two guiding principles. In the first place, the apprentices who attend the school do so partly in Admiralty time. At present the five periods a week are taken, three from the boys' free time and two from Admiralty time, and Admiralty time spent at the school is paid for. In the second place only those pupils are retained who are found to have the requisite ability and industry to profit by the higher instruction; a continuous process of sifting goes on, and the waste of effort is thus reduced to a minimum. Those pupils who go out comparatively early find their position on the wage-earning staff; and, as Sir William White testified, they are altogether different from ordinary workmen, because of the training, short as it may be, which they have had in the school. At the same time, there is sufficient material retained for the training of officers, who will ultimately fill the higher constructional posts. A third principle has been rendered possible of application in recent years, and no candidate is now admitted who has not obtained a sound preliminary education. The number of apprentices in attendance is 180; and the school is arranged in two sections, which attend on alternate days. The full course extends over four years, but there is a weeding-out process at the end of each year. Of those who complete the course a few are selected by examination from all the dockyards for an advanced three-year course at the Royal Naval College, Greenwich, after which they join the Royal Corps of Naval Constructors. The competition for admission to the dockyards as apprentices is severe, and therefore at the outset a careful selection is possible.

The late Lord Spencer, when First Lord of the Admiralty, appointed a committee to consider whether the schools might be abandoned in view of the enormous advances which had been made in the provision for elementary education. Happily for the nation the committee's verdict was unanimously in favour of their retention. The development of to-day in the provision of technical instruction is held by some to justify a fresh proposal for the abolition of the schools, and the transfer of their pupils to the municipal technical schools of the dockyard towns. It is to be hoped history will repeat itself and that the schools will be allowed to continue their unique work. As Prof. Gregory said, they are at least a generation ahead of most of the other technical institutions of this country. Their close association with the dockyard has benefited both. Prof. Worthington pointed out how the problems of the dockyard are brought to the schools for solution, and he also dwelt upon the interest and pride which the rank and file of the yards take in the schools. To sacrifice a century-old tradition for the sake of saving a few thousand pounds would be a deplorable mistake, particularly at this juncture, when the Admiralty's example will be most valuable to administrators and educationists, who have good reason to be dissatisfied with the condition of technical education in the country generally.

SOME ENGINEERING PROBLEMS AND THE EDUCATION OF ENGINEERS.[1]

IT is a consequence of the scientific basis of engineering that it is international, not national. Scientific advances are not restricted within political boundaries. If we gave the world the steam turbine, Germany returned us the gas engine and Diesel engine. Ability to appreciate the value of new discoveries, and readiness to take advantage of them, depend as much on a widespread scientific education as the making of the discoveries themselves.

My distinguished predecessor, out of a long and varied experience in the development of the most modern of the many branches of engineering industry, discussed the economic conditions of production on which successful manufacture depends. It will be more natural to me to deal with some of the technical principles on which the successful design of engineering structures is based.

[1] From an address delivered to the Institution of Civil Engineers on November 7 by Dr. W. C. Unwin, F.R.S., president of the Institution.

Strength of Materials.

The object of a study of the strength of materials is to determine the proper dimensions to be given to parts of machines or structures, in order that they may resist the straining actions to which they are subjected without breaking or prejudicial deformation. It is a modern study, for the earlier architects and builders seem to have had no definite knowledge; only it may be noted that the earliest buildings were the most massive. The Egyptian columns were not more than five or six diameters in height, the Greek about nine. Mediæval buildings depend more on considerations of stability than of strength; but there are mediæval columns carrying arches which are twenty-six diameters in height.

So far as we know, however, Galileo (born 1564, died 1642) was the first man of science definitely to consider strength. He found that a rod of copper suspended vertically might have a length of "4800 arms," or, say, yards, before breaking in tension by its own weight—a reasonable result. Having no conception of elasticity or of variation of stress due to variation of deformation, he seems to have assumed that bodies always broke by tension, and that tension was uniform at the surface of fracture. Applying these notions to determine the strength of a cantilever, he supposed the whole cross-section would be in tension uniformly distributed. He arrived at an equation for bending strength which for rectangular sections is right in form, but affected by an erroneous constant; and he acutely deduced the result that, while a model of a structure might be strong enough to carry a load, the structure itself might be so large as to break by its own weight. This is the germ of the law of a limiting span for bridges. On the same false assumptions Grandi, in 1712, published elegant and correct demonstrations of what we know as solids of uniform resistance to bending. It is not the first instance in science of false assumptions leading to partially correct results.

It was not until 1660 that Robert Hooke discovered the fundamental law that stress is proportional to strain in elastic materials. It was not until 1680 that anyone made further experiments on the strength of materials. Then Mariotte made rough tests of very small bars of wood and glass strained in various ways. He first perceived that in flexure part of the cross-section is in compression and part in tension, and placed the neutral axis for a rectangular bar at half the height, correcting Galileo's result. It was not until 1776 that Coulomb determined the position of the neutral axis for simple sections, and not until 1824 that Navier determined it for all sections.

In 1729 Muschenbroek, at Leyden, published the results of what may be considered the first tests of materials made with precision. He made tension and bending tests, and tests of long columns, but on a very small scale. Perronet, occupied with the construction of the Bridge of Neuilly, in 1758 constructed the first comparatively large testing-machine, a machine capable of applying a stress of 18 tons. Rondelet, in 1787, constructed a testing-machine with knife-edges, and with a screw arrangement for taking up the deformation of the test-bar. It was the first machine containing in principle all the essential elements of a modern testing-machine. Labardie, soon after, constructed a 100-ton machine for the Port of Havre, and Girard carried out with it the first tests on a large scale of the elasticity of materials. In 1813 and 1817 Brunton and Company and Captain Sam Brown constructed cable-testing machines.

Theory of Elasticity.

A very great step in the simplification of the mathematical expression of formulæ of strength of materials was taken by that very remarkable English physicist Thomas Young (1773–1829), who defined the coefficient of direct elasticity, or Young's modulus, and first considered shear as an elastic strain. The time had come for the development of a general theory of elasticity. Navier, in 1827, first investigated the general equations of equilibrium of an elastic solid, starting from an assumption as to the molecular constitution of matter. Navier's equations are still accepted, though part of his reasoning is considered to be unsound. At the same time, Cauchy founded the theories of stress and strain, and Lamé and Clapeyron made important developments.

Reverting to experimental work in this country, early in the last century George Rennie made investigations of the resistance of structural materials, and Peter Barlow made experiments on the strength of timber at the Dockyard and at the Arsenal. This led to his association with engineers; and he assisted Telford in calculations for the Menai Suspension Bridge. His "Essay on the Strength of Timber," in 1817, when developed in later editions, may be regarded as the first general treatise in English on the strength of materials.

Down to about the end of the first quarter of the last century most of the knowledge of strength of materials was due to the work of Continental engineers and physicists. Then an advance was made here. Thomas Tredgold in 1820 published "A Treatise on the Principles of Carpentry." This dealt scientifically and practically with all the then known data of resistance. His book on the steam engine, dealing specially with questions of strength, was published in 1827, and republished down to 1850. It has been rather a fashion amongst elasticians to ignore or depreciate the work of Tredgold. But he had a practical insight into what was important and what was negligible in engineering problems greater than that of writers with more ample mathematical resources, and he rendered essential services to the engineers of his time.

A little later Prof. Eaton Hodgkinson began the researches on strength of materials which give him a foremost place among careful experimenters. He is credited with the discovery of permanent set and of the position of the neutral axis. His paper of 1830 on iron beams, and that of 1840 on columns, were very valuable contributions to practical science.

There is not time to trace further the history of the science of strength of materials. Experimenters and laboratories in the last fifty years have increased enormously, and theoretical investigations have been pushed to great lengths. But I wish to take the opportunity of paying a tribute to one who seems to me the prince of observers in this branch of science. I mean the late Prof. Bauschinger, of Munich, professor of mechanics and graphic statics at the Technical High School at Munich for twenty-five years. There he established a laboratory, rather more for research than instruction, where engineering experiments were carried out with a thoroughness and delicate accuracy never previously equalled. In 1868 he published the result of indicator observations. But his special field of work was that of tests of materials. He created the first public laboratory for this purpose. He first applied Gauss's method of reading by reflection in instruments for measuring the deformation of bodies when strained.

Amongst many researches remarkable for their extent it is only possible just to mention one on cements and cement and lime mortars, demonstrating, amongst other things, the importance of fine grinding, and one on the building stones of Germany. His researches on timber first indicated the precautions necessary for securing comparable results, especially the law of variation of strength with moisture. He carried out many researches on cast iron, wrought iron, and steel, especially some with reference to the variation of the position of the elastic limit under different conditions of straining. Perhaps one of his most important achievements was the foundation of the International Association for Testing Materials.

Testing Materials for Quality.

Down to the middle of the last century the only generally used tests of the quality of iron and steel used in construction were bend-tests, and in certain cases shock-tests. Such other researches as were made were directed to a different object—either to determine the constants in formulæ on which engineers relied or to prove the sufficiency of complete structural members. It was the introduction of Bessemer steel, and cases of unexpected failure of steel structures, which forced on engineers the necessity of systematic tests of quality. An important series of tests carried out by the late Mr. D. Kirkaldy in 1860 led to the adoption of a tension-test as the usual test of quality. Its special merit is that exact figures can be specified for elastic limit, resistance to fracture, and elongation.

With the introduction of definite tests, the importance of accurate and reasonable specifications became urgent. Recently the work of the Engineering Standards Committee has done very much to guide the engineer in securing trustworthy material without imposing conditions too irksome or costly on the producer. Hence it has come about that the testing engineer has been created, having functions partly as an investigator of the properties of materials, partly as adviser of manufacturers, and partly as inspector of material.

Application of the Science of Strength of Materials to Practice.

The general object of the accumulation of experimental and theoretical knowledge of strength of materials has been to determine the minimum amount of material and the best disposition of it in machines and structures to secure safety. Putting it another way, by theory the stress conditions due to any given straining action can be calculated; then it has to be determined what is the greatest permissible working stress, and in what way does it depend on such physical properties of the material as can be ascertained by testing.

The oldest, and still the most common, method of proceeding is to reduce the straining actions to simple tension, thrust or shear, by calculations based on the assumption of Hooke's law, and to provide material enough to limit the intensity of these stresses to a fraction of the breaking strength of test-pieces similarly strained. The ratio of the breaking strength to the working strength is termed the factor of safety. In by far the largest number of cases with which an engineer has to deal, the breaking strength of a structure cannot be calculated, for Hooke's law ceases to be true for stresses much below the breaking stresses. Hence the engineer sometimes proceeds one step further. He tests a scale model of a structure to breaking, and from this deduces the breaking load of the full-size structure by the law of similarity.

In the case of complex structures, the determination of the exact maximum stresses in which are beyond the resources of mathematical analysis, the value of model experiments is unquestioned.

Now it is easy to show that the ratio of the breaking stress to the working stress, or the breaking load of a girder to the working load, is not a real factor of safety; the point at which danger occurs in different cases is not a fixed fraction of either the real or the calculated breaking load. It has even been contended, with some plausibility, that the fashion of dividing the breaking stress by a factor to find the working stress is a barbarous method. The factor must be varied for different conditions, and can only be fixed empirically.

The ductile materials chiefly used in construction *yield* or suffer a large deformation at about half to two-thirds of the breaking stress. The deformations, if the yield stress is exceeded, would be, at least in very many cases, far too large to be tolerated in either machines or structures. If the yield stresses are taken as the limits of safety, then the real factor of safety is only about half the ratio of the breaking to the working stress. Further, the ratio of the yield stress to the breaking stress is not a very constant ratio.

Shall we, then, drop the breaking strength and adopt the yield-point as the measure of the constructive value of a material? Many constructive materials, such as stone, timber, and cast iron, have no yield-point. Besides, even for ductile rolled material, such as mild steel, the point ordinarily determined as the yield-point is not a very fixed point for a given material. It depends a little on the rate of loading. Yielding really begins at the elastic limit, a point below the yield-point, spreading along the bar and becoming general over the bar at the yield-point.

Some writers assume that the elastic limit as determined in a tension test is the real measure of the constructive strength of a material; but I am not sure that this is not, when rigidly examined, the most ambiguous and elusive of all the measures proposed. In what sense, then, is the elastic limit found in a tension-test to be understood?

No doubt there are cases where the primitive tensile elastic limit does fix a superior limit to the stress consistent with safety. But it cannot be taken generally as an exact

measure of constructive value, though it certainly is a valuable indication. Further, the elastic limit in compression is seldom observed, and the elastic limit in shear is experimentally almost unknown. Yet resistance to shear is probably for ductile materials the most important element of constructional value. It would be interesting to have the elastic limit in torsion of thin tubes accurately determined.

Hence, whether we take the breaking stress, the yield stress, or the primitive elastic limit, we have not found a satisfactory rational basis for measuring the constructive strength of a material. There is not a fixed ratio between the greatest safe working stress and either of these. But I do not wish to be understood as depreciating the value of the determination of breaking stress, yield-point, and elastic limit in testing materials.

Valuable as are the data of breaking strength, yield-point, and elastic limit determined in a tension test in influencing the judgment of the engineer, they do not furnish any purely rational rule for fixing the working stress for designers. Experience in similar cases must always be the ultimate appeal.

Compound Stress.

So far, all that has been said relates to cases of simple tension, thrust, or shear. But in a very large number of cases two of these stresses are combined. In such cases the theory of elasticity furnishes the principal stresses and the principal strains; but the question, What is the criterion of safety? involves another of the unsolved problems of engineering. Two schools arose amongst theorists, one holding that the maximum stress, the other that the maximum strain, determined fracture. For simple stresses, either assumption leads to the same result. It is not so with compound stress. Very early Coulomb suggested that fractures would be determined by shear, as is the case with cast iron under compression. The subject is now under investigation experimentally, and, speaking generally, it seems that for ductile materials the material gives way at some limit of shearing stress, while for brittle material in tension the principal stress is the best criterion of strength.

Comparative Structural Value of Materials.

It is only when comparing two different materials that an engineer needs to consider relative constructive value, and then he bases his judgment on all the properties of the material. Ordinarily, the safe working stress is fixed by experience in similar cases, theory helping mainly in explaining why in different cases different stresses are suitable. The history of engineering design is a history of experiments in construction, in which by trial and error right proportions have been found; and in the settlement the different relative importance of cost and weight enter into the question, as well as considerations of mechanical strength. The fact that scientific data and rational, or semi-rational, formulæ are conveniently used should not be allowed to conceal the fact that an empirical element always enters into the solution.

New designing is really a process of comparison, in which the engineer extends experience in known cases to new conditions; and the problem is in what proportion dimensions must be varied to allow for differences of size, of material, of loading, of speed, or of form.

Most practical problems in designing for strength reduce themselves, if traced to their foundation, to applications of the law of similarity. At a time when steam engines all worked at about the same steam pressure, it was broadly stated that the drawings of an engine of any size could be used for constructing engines of any other size by merely altering the scale of the drawing. So-called mechanical instinct is, no doubt, really reasoning based on the law of similarity.

In the case of machines, another consideration enters. The weight stresses are not usually important, but the inertia stresses due to variation of velocity or direction of motion are very important. The stresses in a fly-wheel rim due to radial acceleration are proportional to the square of the rim velocity, whatever the cross-section. Hence fly-wheels are equally safe in this respect if the rim velocity is the same, or if the rotations per minute are inversely as the diameters.

Engineering Education.

I turn to another subject, which seems to be appropriate in a year in which the institution has held a conference on the education and training of engineers. An important change is going on in all types of education. In all it is being recognised that they should be such as to afford a training for the duties of life. The term "engineer" is used in such wide and loose senses that it is necessary to be explicit as to one's point of view. There are vocations associated with engineering work for which no special training is absolutely required beyond that of the factory or commercial office, or for which any other training required is different and more limited in scope than that of the professional engineer or director of engineering works. But the conference considered the case of those who aim at becoming ultimately professional engineers, that is, men who advise, design, and direct the execution of works of civil engineering in the wide sense in which that term is used in this institution. If the course of training of such men is provided for, the less complete training of men for lower grades of service is not likely to be wanting. But I do not think that we distinguish sufficiently at present the different type of education required for leaders and subordinates, the heads and the hands.

It must be recognised that the professional or consulting engineer is not solely concerned with technical problems, though as to these he must be an expert. But he is more and more concerned with economic, legal, and commercial problems of much intricacy, and must be prepared to meet men of affairs and of liberal education on an equal footing.

Now the earlier great engineers in this country had no formal technical training; indeed, very little general education either. Brindley, George Stephenson, Fairbairn, had only parish-school education; Smeaton, Telford, and Watt only grammar-school education. They picked up even their practical experience gradually and casually. They differed in this from their contemporaries in France. Perronet, Gauthey, Rondelet, and Navier, for instance, were of a more academically educated type.

It is, no doubt, due in part to such early conditions of English engineering, in part to the narrow and unscientific character of secondary and university education in this country, that until recently the education and training of engineers has been so unacademic and unsystematic.

Preliminary Education.

A very great obstacle to the progress of technical education in this country has been the want of any definite aim—the unsuitable character and poor average quality of our secondary education. Grant whatever can fairly be urged as to the honourable spirit, the pluck, and resourcefulness of boys from the better public schools; grant also the value of dead languages as a means of culture for those who really master them, it must still be recognised that the average boy, to some extent, still leaves school sadly unfitted for any form of higher education. The success of the clever and brilliant few, educated for university prizes, has obscured the poor quality of the intellectual equipment of the average many.

Happily, if the state of things is not yet satisfactory, if secondary education is still unorganised, and the schoolmaster is only partially converted, still science has obtained a footing, and school-leaving and other examinations have secured that the average lad is better taught.

It was partly a cause, partly a consequence, of defective school education that the great universities have not addressed themselves, in a responsible and scientific manner, to securing that candidates for admission to higher courses had reached a reasonable standard. Still less were the engineering schools, with one or two exceptions, able to insist that students were properly prepared for technical instruction. It is only recently, and partly under pressure from the institution, that a fairly satisfactory entrance examination has been prescribed in some English and colonial engineering schools. To admit lads with imperfect preliminary education to advanced instruction lowers the whole standard of work in the classes.

An erroneous opinion has prevailed that technical instruction requires little or no literary and scientific education to

prepare the way for it. I noticed the statement in the address of the Chancellor of St. Andrews, on the occasion of the quincentenary of the University, that the test now imposed for entrance would in some respects compare not unfavourably with that for graduation about half a century ago. In the best engineering schools a similar change has occurred, and should, indeed, make further progress. The possibility of effective technical teaching depends on suitable previous preparation; and on this point the committee of the institution in 1906 came to very decided and definite conclusions, and laid down explicitly a scheme of school education for engineering students.

Technical Education.

It is only in modern times that universities came to be regarded as solely concerned with a general liberal and, except as regards medicine, an entirely non-technical education. "The colleges were in their inception," says Mark Pattison, the rector of Lincoln, "endowments not for the elements of a general liberal education, but for the prolonged study of special and professional faculties by men of riper age"; and he lamented that they no longer promoted the researches of science or directed professional study. That state of things is happily changing, especially in the modern provincial universities.

The new vocation or profession of engineering grew up in this country with very little academic encouragement. It is true that after 1840 engineering schools were attached to a few universities. But they were generally unendowed, unequipped, or uninfluential. The most distinguished of them was that at Glasgow, where the Regius professorship was held by Gordon and Rankine.

Meanwhile, in France and Germany there had long existed remarkable engineering schools with distinguished teachers. The Paris Ecole Polytechnique was instituted in 1794, the Ecole des Ponts et Chaussées in 1795, the Ecole des Mines in 1778, the mining school at Freiburg, where many foreigners obtained education in 1765. In the first quarter of the nineteenth century were established the technical high schools of Karlsruhe, Hanover, Berlin, Dresden, Vienna, and the École Centrale at Paris. The great Zürich Polytechnicum dates from 1854.

With one exception, I do not think there were any engineering schools in this country with what could be regarded as a reasonably complete and satisfactory curriculum or equipment before 1870. In giving this date I am passing over the system of education adopted by the Admiralty for naval engineers and architects in 1843. Sir Alexander Kennedy established the first college engineering laboratory in 1878, and from that may be dated the beginning in this country of a necessary equipment of engineering schools. There is now a number of university engineering schools, or schools of university rank, directed by teachers of eminence not only in science, but in practical engineering, with systematic courses of instruction covering broadly all branches of engineering up to the graduate stage, and of a thoroughly practical character. Quite recently a beginning has been made of post-graduate instruction of a specialised character. It is only in a post-graduate course that engineering students can be usefully or efficiently employed in research.

Advanced Education and Practical Training.

I cannot help thinking that there is a tendency amongst some practical engineers to suspect those of us who are interested in formal technical instruction of indifference to the value of practical experience. But surely that is a mistake. Most engineering professors are themselves engineers of considerable practical experience. What, in fact, they do somewhat doubt is the value of so much practical experience as an ordinary apprentice gets who goes straight into works without technical training, and who has to pick up his knowledge as he can. At the best, his experience is a narrow one. Some of the jealousy occasionally shown as to college training seems to arise from the feeling that it interferes with the traditional English system of articled pupilage, which, so far as I know, hardly exists in any other country. It does seem to me that the old apprenticeship system for professional engineers, taken by lads direct from school, was uneconomical, wasteful of time, involving unnecessary drudgery, and in some respects unfair.

There is another consideration as to the pupilage system as it existed forty years ago. It was suitable only for the wealthy. But many of the most hard-working, capable, and even brilliant students are not of the wealthy class. In these days there are ladders from the elementary school to the university and the technical college. It would be a loss to the country and the profession if really able, but comparatively poor, students could find no way to employment. In this competitive time we can least of all afford to neglect or waste intellectual ability.

The institution has by its system of examinations expressed its view of the importance of such theoretical and practical technical education as it is the object of technical schools to give, while at the same time it has done what is possible by its by-laws to encourage or require a term of pupilage or apprenticeship as a means of acquiring experience. Further, in the report of the committee of 1906, while insisting on the value of pupilage or apprenticeship, it has most definitely expressed the opinion that a three years' course in a technical college is equally necessary, and should form an integral part of the training of an engineer; and this conclusion was endorsed by a large majority of the engineers who were consulted by the committee.

The question arises, and I think it is a serious one, how far engineers now are taking any steps to carry out the recommendations of the institution committee as to the requirement of preliminary training antecedent to pupilage. It is clear that young men will not incur the expense, the labour, and the delay of a college course if it gives them no advantage in entering the profession.

Some inquiries were lately made by the institution of more than a hundred engineers in various branches of engineering as to the conditions on which they accepted pupils or apprentices. In a few cases it appears that pupils or apprentices are required to have passed an examination equivalent to the Studentship examination of the institution. In a very few cases the possession of a degree is accepted as a reason for shortening the period of apprenticeship. But what is desirable is that a lad should reach the standard of the Associate Membership examination or the examination for a first degree before entering on pupilage. If he does not he will only be able to reach it by cramming, which, though not quite useless, is much inferior to a systematic course of study. As a matter of fact, however, within my own knowledge the colleges have more influence than these returns seem to show; and, especially in the case of the provincial universities, local patriotism ensures preference to men trained in the local university.

The Transition from College to Practice.

It seems to me that the great efforts made during the last forty years, and the expenditure incurred, largely from private sources, in establishing engineering schools lack in one respect full recognition by the profession. Many engineers have given generously in money and in time; but engineers in general might do more in facilitating the transition from school to works. With an experience of twenty years, I believe that more organised and recognised relations between the schools and offices and works are desirable and possible. The most difficult part of a young engineer's career is the step between college and full capability in some special branch. No engineering school can prepare students completely for any special position in the engineering field without very undesirable narrowing of the scope of the instruction. Two years of pupilage or employment is desirable as a transition period; and the difficulty is that generally engineers expect that someone else should have the task of rounding off the college training. Even in the United States it is perceived that, to make technical education effective, the employer must shoulder a part of the load imposed by the old apprenticeship system, which in the United States has been to a great extent thrown on the schools.

I am therefore much in sympathy with the proposal that there should be an endeavour to produce some coordination between the colleges and employers by making an inquiry as to the conditions under which well-qualified

students may be able to get practical training, whether they seek employment later in the mechanical or electrical branches of engineering or in constructional or administrative work. Some scheme might be evolved linking the colleges and the manufacturing, municipal, or other public works, so far that the first stage of practical experience might be gained under conditions less haphazard than at present. No doubt college graduates who want to fit themselves for service in India or for starting in private business are fairly asked to pay for the privilege of entering works or office. But in other cases well-trained students who are quite capable of being useful might very well be taken on easy terms, for a trial of a year or two, in the expectation that they would remain afterwards as valuable assistants. In the engineering departments of municipalities greater facilities for apprenticeship might be given. By choosing technically well-educated lads and directing their practical training, they would form a loyal staff, ultimately more competent and useful than others less educated, but selected as more immediately useful. Further, it is now proved that technically educated lads are very fit, with some experience added, for the commercial branches of an engineering business.

If a university degree or college diploma is to be taken as a qualification for beginning an engineering career, it must not be overlooked that degrees and diplomas are of very varied value, and that one great function of a college is to distinguish the more and the less capable amongst its students.

I believe there are no schools of university rank where the work is more strenuous, the methods more practical, or new ideas more welcome, than in the best of the engineering schools of the day.

I have touched on various subjects, unavoidably in a short address, with some one-sidedness. We have been driven lately to recognise how intimately the very existence of society as now constituted depends on the work of the engineer. It is because I have come to believe in the importance of coherent and systematic instruction and in the value of the play of mind on mind and the influence of generous rivalry, best enjoyed at a plastic and impressionable age during studentship, that I have ventured to urge the claims of engineering schools in preparing the engineer for service in shaping the destinies of the Empire.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—A scholarship of 150*l.* a year for three years has been awarded by the Board of Agriculture and Fisheries to Mr. Gilbert E. Johnson, a student in the department of zoology. This scholarship is one of the number recently founded by the Board with the object of encouraging research in agriculture. Mr. Johnson is at present engaged in research in connection with the subject of eel-worms.

OXFORD.—The statute allowing honour students in mathematics and natural science to dispense with Greek in Responsions passed Congregation on November 7. No canvas had been made on either side, and the division, showing 33 for the statute and 11 against, was without any particular significance. The real struggle will take place when the measure is submitted to Convocation, the ultimate legislative authority of the University. This will probably take place before the end of the present term.

SIR HENRY CRAIK, K.C.B., M.P., has accepted the principalship of Queen's College, London, in succession to Canon G. C. Bell, resigned.

AT a meeting of the governors of the South-Eastern Agricultural College, Wye, held on November 6, it was decided to approach the Board of Agriculture and the Development Commissioners with regard to the foundation of a research institution for fruit-growing, including the practical treatment of plant diseases, in the County of Kent, and also to apply for a grant in aid of the proposed extension of the college buildings.

THE first meeting of the Association of Teachers of Mathematics for the south-eastern part of England will be held at Tonbridge School on Saturday, November 25, at 3 p.m., when the inaugural address will be given by the president, Dr. A. N. Whitehead, F.R.S. This meeting will be open to all who are interested in the teaching of mathematics Further information can be obtained from the honorary secretary of the association, Tonbridge School, Kent.

WE learn from *Science* that the will of Miss E. C. Woerishoffer leaves 125,000*l.* to the trustees of Bryn Mawr College, of which she was a graduate. From the same source we find that the estate of the late Mr. John S. Kennedy is even larger than has been previously announced. The share of Columbia University is 486,000*l.* New York University and the Presbyterian Board of Aid for Colleges each receive 195,000*l.*, and Robert College, Constantinople, 370,000*l.* The specific bequests, not dependent on the size of the estate, include 20,000*l.* each to Yale, Amherst, Dartmouth, Bowdoin, Hamilton, and Glasgow.

AT a Congregation of the University of Wales, held in Bangor on November 10, the following degrees were conferred, *honoris causa*:—For the degree of Doctor of Science, Prof. Conwy Lloyd Morgan, F.R.S., sometime Vice-Chancellor of the University of Bristol, and Sir William H. Preece, K.C.B., F.R.S., sometime electrician to the General Post Office. For the degree of Doctor of Laws, Dr. William Thomas Edwards, J.P., and Sir Isambard Owen, Vice-Chancellor of the University of Bristol, sometime Senior Deputy Chancellor of the University of Wales. For the degree of Master of Arts, Miss Isabella Cleghorn, distinguished for her services in the cause of education.

"THE Moral Influence of a University Pension System" forms the subject of an article in *The Popular Science Monthly* for November by Dr. Henry S. Pritchett. It will be remembered that the author is president of the Carnegie Foundation for the Advancement of Teaching, which has provided for the staffs of American universities and colleges a liberal scale of retiring pensions. Although the system has been organised on a non-contributory basis, Dr. Pritchett seems, on the whole, inclined to favour the contributory system. Probably the conditions are somewhat different in America from those prevailing in this country, where Government old-age pensions have been arranged on a non-contributory basis, and where the main reason for not adopting the same course in our universities has been on financial grounds.

THE present session is the thirtieth during which the City of Bradford Technical College has been at work. The new calendar, which has been received, gives full particulars concerning the very complete provisions which have been made to provide technical instruction in connection with the various industries of the West Riding. The buildings have been greatly extended in recent years. Among other important developments we notice the dye-house is now ready in which the material required for, and produced in, the textile department will be dealt with. The equipment is such that students will have the opportunity of carrying out practical work of an instructive character. The machinery is capable of dealing with loose wool or cotton, slubbing, yarns of all materials, warps, and piece goods. The machines represent the latest practice. In connection with the extension, it was decided to put down a plant for the engineering department which, although primarily intended for educational purposes, would at the same time serve for supplying light and power to the present building, the new extensions, and the school of art. This is probably the most important step in the history of the department which has yet been taken. We notice also that a systematic course in sanitary science, suitable for sanitary and other inspectors in the West Riding, has been arranged to comply with the requirements of the Sanitary Inspectors' Examination Board, and that the college has been placed by the Board of Trade on the list of technical institutions recognised by the Board for the purpose of the regulations relating to the examinations for engineers in the mercantile marine.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 9.—Sir Archibald Geikie :.C.B., president, in the chair.—Sir William **Crookes**: 'he spectrum of boron. The physical properties of the lement boron are almost unknown, notwithstanding the fforts of many chemists who have worked on the subject. Ioissan, who came nearest to obtaining the pure element, nly succeeded in getting it in the form of an amorphous owder. He said it was not possible to melt or volatilise t in a carbon crucible or arc as it was changed into carbon oride, and concluded that boron passed from the solid to he gaseous state without becoming liquid. Recently Dr. Veintraub, of the General Electric Company, U.S.A., has ot only obtained boron in a state of purity, but has preared it in a fused homogeneous state. His process onsists in running an alternating-current arc between vater-cooled copper electrodes in a mixture of boron hloride vapour with a large excess of hydrogen. The oron agglomerates on the ends of the electrodes, where t grows in the form of small rods. After a while the arc uns between two boron electrodes; and if the current is of roper value the rods melt down to boron beads, which ventually fall off, whereupon the same process repeats tself. The first specimens received from Dr. Weintraub vere deposited from a vaporous state from boron chloride nd hydrogen in the manner described. Subsequently he indly sent the author some lumps of fused boron which ad been prepared from magnesium boride. This boride issociates at a relatively low temperature (1200°), especilly *in vacuo*, and with rapidity at 1500°. The fusion is ffected between copper electrodes, the affinity of copper or boron being so slight that it can be directly fused on o the electrode without being contaminated with copper. nother way of fusing boron is in what Dr. Weintraub alls a mercury arc furnace, based on the fact that most efractory bodies, such as tungsten, tantalum, boron, &c., ave no affinity whatever for mercury. The result of the uthor's work on boron is to show its photographed specrum consists essentially of three lines, the wave-lengths of which, according to accurate measurements, are 3451·50, 497·83, and 2496·89. For more easy comparison the wavengths of these lines measured by different observers are iven below in a tabular form:—

Hartley (1883)	3450·3	2497·0	2496·2
Rowland (1893)	—	2497·821	2496·867
Eder and Valenta (1893) ...	3451·3	2497·7	2496·8
Exner and Haschek (1897) ..	3451·4	2497·8	2496·88
,, ,, (1902)...	3451·49	2497·79	2496·87
Hagenbach and Konen (1908)	3451	2498	2497
Crookes (1911)	3451·50	2497·83	2496·89

'he fourteen other lines given by Eder and Valenta, and ne five other lines given by Exner and Haschek, failed to ecord themselves on the photographs, notwithstanding xcessively long exposures given in the attempt to bring ut additional boron lines. The most interesting property f solid boron is its extraordinary rise in electric conuctivity with a slight increase in temperature. A piece f melted boron measured by Dr. Weintraub, which at ne room temperature (27°) had a resistance of 5,620,000 hms, dropped to 5 ohms at a dull red heat. Another oteworthy property of melted boron is extreme hardness. t comes next to the diamond in hardness, a splinter easily cratching corundum. Its fracture is conchoidal, and no ecided crystalline structure is seen under the microscope. 'he agglomerated boron deposited in the arc from boron hloride and hydrogen is, on the contrary, highly crystalne.—Hon. R. J. **Strutt**: A chemically active modificaon of nitrogen produced by the electric discharge: II.) Oxygen destroys active nitrogen, but does not combine ith it. Hydrogen has no action. (2) Active nitrogen, in acting with nitric oxide to form the peroxide, gives the ame greenish-yellow flame with continuous spectrum which nay be obtained by stimulating oxides of nitrogen in other 'ays. (3) The reaction just mentioned is used to deterine the percentage of active nitrogen present in ordinary itrogen as it leaves the discharge. The result found is bout 2·5 per cent., much higher than was formerly supbsed. (4) When dilute phosphorus vapour is introduced ito glowing nitrogen it does not react at once. It is not until some time after the glow has completely disappeared that the nitrogen gets into a state in which it can react with phosphorus. (5) The glow has a large electrical conductivity, comparable with that of a salted Bunsen flame. The ions are liberated in the glow, not merely carried forward from the original discharge. This ionisation is, as a rule, not very greatly affected when the spectra of other substances, such as metals or cyanogen, are developed by the active nitrogen in the space between the testing electrodes. (6) None of these spectra are visibly diminished in intensity when large electromotive forces are applied to remove the ions. (7) Ozone can in some cases develop metallic spectra when mixed at comparatively low temperatures with the metallic vapour.—Sir J. **Dewar**: Production of solid oxygen by the evaporation of the liquid.—Sir J. **Dewar** and Dr. H. O. **Jones**: The gaseous condensable compound, explosive at low temperatures, produced from carbon disulphide vapour by the action of the silent electric discharge: II.—Dr. T. H. **Havelock**: Optical dispersion: a comparison of the maxima of absorption and selective reflection for certain substances. This paper contains a discussion of various wave-lengths associated with each dominant region in a general type of dispersion formula. It is shown how the maxima of absorption and of selective reflection are, in general, separated from each other and from the wave-length corresponding to the natural vibrations in the molecule. Formulæ are obtained for some of these maxima in terms of the constants of the dispersion formula, and are confirmed by comparison with available experimental results. To estimate the magnitude of the differences in question, a numerical study is made of regions of selective absorption and reflection for carbon disulphide, rock salt, and sodium vapour; in particular, for rock salt it appears that the maximum of selective reflection in the infra-red is displaced considerably from the maximum of absorption and from the dominant wave-length of the dispersion formula. —Dr. T. H. **Havelock**: The influence of the solvent on the position of absorption bands in solutions. According to Kundt's rule, the effect of the solvent is to displace the absorption bands further to the longer wave-lengths the greater the refractive or dispersive power of the solvent. By using a suitable type of dispersion formula this rule is given a definite theoretical expression, and various experimental results are examined from this point of view. Although effects are complicated, in general, by molecular changes, it is possible to estimate in some cases how much can be ascribed to the operation of Kundt's rule.—Prof. F. G. **Donnan** and Dr. J. T. **Barker**: An experimental investigation of Gibbs's thermodynamic theory of interfacial concentration in the case of an air-water interface. The "surface" concentration of a dissolved substance in excess over that in the bulk of the solution is given by Gibbs's equation $\Gamma = -d\sigma/d\mu$, where Γ = excess of solute per unit of interface, σ = interfacial tension, μ = chemical potential of solute. Assuming the simple osmotic law of van 't Hoff for the solution, the above equation can be written in the form $\Gamma = -\frac{c}{RT}\frac{d\sigma}{dc}$, where c = bulk concentration of solute. The authors have tested this equation by measuring independently Γ, c, and $d\sigma/dc$ for the case of an air-water interface. The substances examined were pelargonic acid and saponin. The value of Γ was determined by finding the change in concentration of a given volume of solution caused by bubbling through it a known volume of air in the form of a known number of very small air bubbles. Steady streaming of the liquid was prevented by breaking up the column of liquid into a number of eddy chambers. The extremely small changes of concentration thus produced in excessively dilute solutions were measured by means of a dropping pipette, the same apparatus being also employed to measure $d\sigma/dc$. The values of the two members of Gibbs's equation were found to be in fairly good agreement, considering the difficulty of the experiments. In the case of aqueous solutions of pelargonic acid of concentrations varying between 0·008 and 0·0024 gram per 100 grams of water, the average value of Γ found experimentally was in round numbers one ten-millionth of a gram per square centimetre of interface at 15° C. In the case of saponin the values found were somewhat greater.

Zoological Society, October 24.—Sir John Rose Bradford, K.C.M.G., F.R.S., vice-president, in the chair.—Bruce F. **Cummings**: Distant orientation in Batrachia, based on observations and experiments made by the author in North Devon. Two species of newts had been used for the experiments, and the results obtained lent support to the hypothesis that these batrachians possessed a homing faculty, but no very definite instinct for detecting water, even from a short distance. Of the factors discussed in connection with amphibian migration, it was suggested that in regard to newts a combination of their homing faculty and their marked tendency to walk downhill was chiefly of assistance to them in finding water in which to breed.—Oldfield **Thomas**: Mammals collected in the provinces of Sze-chwan and Yunnan, western China, by Mr. Malcolm Anderson, for the Duke of Bedford's exploration of eastern Asia. The paper formed No. xv. of the series, and would be the last on Mr. Anderson's specimens, as he was now returning finally to America. During his work on the exploration he had obtained 2700 specimens, besides many birds, and had quite revolutionised our knowledge of the area explored. The present collection, given, as before, to the National Museum by the society's president, consisted of 160 specimens, belonging to thirty-three species.—E. P. **Stebbing**: Game sanctuaries and game protection in India. The author discussed the question of the formation of game sanctuaries and what had been already done in this direction in various parts of the country. Suggested additions to the proposed New Indian Game Act were given, and "close seasons" for certain species recommended as being necessary for the preservation of the game of the country.

Challenger Society, October 25.—Dr. G. H. Fowler in the chair.—Prof. D'Arcy W. **Thompson**: The scales of the herring as an index to age. In the herring, the rings or zones borne by the scales, which are constant in number for the same individual, and are undoubtedly correlated in some way with the size and age of the fish, are not, in the writer's opinion, so simply related to the years of life that the age of an individual fish can be determined with accuracy from an inspection of the scales. In any random sample of herring the frequencies of individuals at centimetre lengths and of numbers of rings each forms a probability curve grouped about a single mode. Either, then, the shoal is composed of herrings of uniform age and number of rings, or of various ages and ring numbers mixed in a definite and remarkable manner. While, on the usual hypothesis of each scale ring indicating a year of life, the facts may conceivably be explained as due to selective action of the net, the writer considers that it is more probable that the members of a herring shoal are of the same age.—Dr. W. T. **Calman**: Phototropism and the distribution of marine organisms (opening of discussion).

British Psychological Society, November 4.—Dr. Beatrice **Edgell** and W. Legge **Symes**: A preliminary note on visual flicker.—Dr. F. **Golla**: The vestibule and the concept of space.—J. **Kay**: (1) Apparatus for McDougall's dotting test; (2) apparatus for weight discrimination.

Mathematical Society, November 9.—Dr. H. F. Baker, president, in the chair.—J. E. **Campbell**: The invariants of the linear partial differential equation of the second order in two independent variables.—Colonel R. L. **Hippisley**: Closed linkages.—H. **Hilton**: Invariants of a canonical substitution.—G. T. **Bennett**: The system of lines of a cubic surface.—G. H. **Hardy** and J. E. **Littlewood**: The relations between Borel's and Cesàro's methods of summation.

CAMBRIDGE.

Philosophical Society, October 30.—Sir George Darwin, K.C.B., F.R.S., president, in the chair.—G. R. **Mines**: Note on the mode of discharge of the Cuverian organs of *Holothuria nigra*. The sea-cucumber, *H. nigra*, when irritated emits white conical bodies, the Cuverian organs, which rapidly elongate, shooting through the water while remaining attached at their bases to the animal, and forming long, intensely sticky tubes. These are then disconnected from the animal. The elongation of the Cuverian organs has been attributed to internal water pressure by some, but by others to an intrinsic activity of the t[...] The former view is strongly supported by the facts [pre]sented in this communication. Undischarged Cuv[...] organs removed from the body cavity of Holothuria can [be] made to elongate in a manner exactly resembling [the] normal discharge by injecting them with sea water or o[ther] fluid. The natural discharge of the Cuverian organ[s is] always preceded and accompanied by a rise in the pre[ssure] within the body of the animal, and this pressure re[...] the value needed to elongate an excised Cuverian or[gan]. The arguments which have been adduced in favour of [the] intrinsic activity of the Cuverian organs are shown, [by] further experiments, to lack cogency. An account of [the] work will appear shortly in *The Quarterly Journal [of] Microscopical Science*.—Oswald H. **Latter**: The discha[rge] of spermatozoa by *Unio pictorum*.

PARIS.

Academy of Sciences, November 6.—M. Armand Gaut[ier] in the chair.—E. H. **Amagat**: The internal pressure [of] fluids and the determination of the absolute zero. In [a] previous paper the author has defined a function π = $\left(T\frac{dp}{dt}-p\right)$. It is now shown that the values of π f[or] hydrogen, taken for pressures of 1 and 3 atmospheres, an[d] taking 273 as the temperature of melting ice on the ab[so]lute scale, obey perfectly the law of the square of th[e] volume, and this is not the case if 273·1 or 272·9 [is] assumed. It is possible to look at the problem from [a] different point of view, and determine the absolute zer[o] from the condition that, starting with well-determ[ined] coefficients of pressure under 1 and 3 atmospheres, th[e] values of π should rigorously satisfy the law of the squ[are] of the volume. This gives from the data for hydrog[en] 272·983, for nitrogen 272·999, and for oxygen 272·996 f[or] the absolute zero.—C. **Guichard**: A very extended class [of] triple orthogonal systems.—J. **Meunier**: The conditions [of] production of the Swan spectrum, and on conclusions wh[ich] may be drawn relating to comets which possess this spe[c]trum. The Swan spectrum is regarded as essentially [a] spectrum of oxidation and explosive combustion, and ad[di]tional experiments on this point are described. The Sw[an] spectrum denotes not only the presence of a hydrocarbo[n] but also that of oxygen, and hence oxygen must be pre[sent] in comets showing this spectrum.—A. **Guillet**: An ind[uc]tion-coil interrupter formed of a primary arc.—J. **Guyot**: The differences of contact potential apparent between metal and electrolytic solutions.—Jacques **Danne** [and] Victor **Crémieu**: The quantity of radium emanation di[s]engaged by one of the springs at Colombières-sur-Or[b], Hérault. The amounts of emanation per 10 litres of g[as] have been determined for three springs. One of the[se], the Crémieu spring, is remarkable on account of the lar[ge] quantity of gas spontaneously evolved—43,000 litres [in] twenty-four hours. The amount of emanation disengage[d] in twenty-four hours from this spring is more than doub[le] that of Ax (Viguerie); and, moreover, since 95 per cen[t.] of the gas from the Crémieu spring is carbon dioxide, t[he] concentration in the radium emanation is readily increa[sed] twenty times by simple treatment with alkaline solution. —G. Ter. **Gazarian**: A general relation between t[he] physical properties of bodies: application to densit[ies]. The comparison of physical properties, either at 0° C., [or] at the boiling point, or at corresponding temperatur[es] according to Van der Waals's formula, is not altogeth[er] satisfactory; and in place of these the author proposes t[he] following: at temperatures equally removed from t[he] critical temperatures, the quotients of the numbers r[e]presenting a property for any two bodies whatever are [a] linear function of the temperature. This holds for d[ensi]ties, viscosity coefficients, surface tension, the rectilin[ear] diameter of Cailletet and Mathias, and the latent heat [of] vaporisation. The densities were compared at analog[ous] temperatures (defined as above) of ammonia and pentan[e], carbon monoxide and pentane, benzene and pentane, acet[ic] acid and pentane.—H. **Duval**: The molecular refraction [of] azo-compounds. The molecular refraction of solutions [of] azo-benzene was found to depend to a certain extent on t[he] solvent. The ortho- or meta-position of a substitut[ing] group causes too slight a variation in the refraction

[co]nclude that these compounds have a different constitu[tio]n.—A. **Boutaric**: Cryoscopy in fused sodium thio[sul]phate. $Na_2S_2O_3.5H_2O$ melts at 48·5° C. The tempera[tu]re of equilibrium between the solid hydrates with $5H_2O$ [an]d $2H_2O$ and the solution is 48·2° C. Various organic [su]bstances and salts of sodium give a molecular lowering [i]n this solvent of 44°; salts of other metals produce about [do]uble this lowering.—A. **Besson**: The formation of [hy]drogen peroxide under the silent electric discharge. It [is] proved that H_2O_2 can be formed by the silent discharge [act]ing on moist rarefied air at a moderately low tempera[tur]e, conditions realised in the upper regions of the atmo[sp]here. Although ultra-violet light may be one cause of [th]e presence of hydrogen peroxide in rain water, these [ex]periments prove that electrical phenomena may also be [a] contributory cause.—J. **Bougault** and C. **Charaux**: [La]ctarinic acid. This acid has been shown in a previous [pa]per to be a ketostearic acid. The application of the [Be]ckmann reaction proves the ketonic group to be in the [po]sition 6, the formula being

$$CH_3—(CH_2)_{11}—CO—(CH_2)_4—CO_2H.$$

—J. B. **Senderens** and J. **Aboulenc**: The catalytic [es]terification of the dibasic acids in the wet way. Quanti[ta]tive studies of the formation of esters of malonic, [su]ccinic, oxalic, and phthalic acids in presence of small [qu]antities of sulphuric acid, aluminium sulphate, or [po]tassium bisulphate as catalysts.—A. **Roussy**: The life [of] fungi in the fatty acids. It is shown that moulds which [gr]ow well in a medium containing a certain quantity of [fa]t owe their development rather to the fatty acids than to [th]e glycerol. It is only in rare cases, in particular for [As]pergillus and Penicillium, that glycerol is as good a [me]dium as the fatty acids.—Raoul **Combes**: Researches [on] the formation of the anthocyanic pigments.—J. [Du]**mont**: A new method for the physical analysis of soil. —Louis **Gaucher**: The digestion of casein. Milk is only [co]agulated in the stomach, and the clots reduced to a fine [st]ate of division by the contractions of this organ. The [pe]ptonisation occurs in the intestine, and may even be [co]ntinued in the duodenum. The coagulation of the milk [in] the stomach is not a necessary condition of its digestion. —F. **Houssay** and A. **Magnan**: The wing surface, the [we]ight of the pectoral muscles, and the feeding process in [ce]rtain birds.—A. **Desgrez**: The influence of the chemical [co]nstitution on the toxicity of nitriles and amides. Un[sa]turated nitriles are more toxic than saturated nitriles [co]ntaining the same number of carbon atoms.—E. [Vo]**isenet**: New considerations on the disease of bitterness [in] wines in its relations with the acrylic fermentation of [gly]cerol. The acrylic fermentation of glycerol is at least [on]e of the essential processes undergone by wine when it [de]velops bitterness.—A. **Daniel-Brunet** and C. **Rolland**: [Co]ntribution to the chemical and physiological study of [th]e hepatic gland in cattle.—P. **Mazé**: Experimental [ch]lorosis in maize.—Raphaël **Dubois**: Microbioids.—M. [Fo]**urnier**: The existence of coal at Franche-Comté, at [Sa]int Germain near Lure (Haute-Saône). Details are [gi]ven of the strata found in three trial borings; the coal [fo]und is similar to the Ronchamp coals.—L. **Cayeux**: [Th]e existence of organic remains in the ferruginous rocks [as]sociated with the Huronian iron minerals in the United [St]ates.

HUMAN GEOGRAPHY.

Influences of Geographic Environment. On the Basis of Ratzel's System of Anthropo-Geography. By Ellen C. Semple. Pp. xvii+683. (New York: Henry Holt and Co.; London: Constable and Co., Ltd., 1911.) Price 4.00 dollars net.

THE influence of geology on that part of geography which deals especially with the forms of the earth's surface, and of mathematics on the measurement and representation of that surface, have given a definiteness and precision to the inorganic side of the subject which are less evident in the geographical study of man and of his relations to the region in which he dwells. In German the work of Ratzel has long furnished a basis for the scientific development of this part of the subject, and though his "Anthropologie" is rather a collection of brilliant essays than a logical and even treatment of this vast subject, its influence on subsequent workers has been far-reaching. In English such treatment of the subject in a scientific manner on a like scale has not been attempted, and the organic side of geography has been delayed in its scientific development here by its absence. Miss Semple's volume is therefore particularly valuable, especially as it is not simply a restatement of the principles embodied in Ratzel's work but comprises such amplification of some portions and abridgment of others as were necessary to make a more even presentation of the subject; at the same time as much evidence as possible of typical peoples of all races and all stages of cultural development living under similar geographical conditions has been incorporated.

A short account of geographical factors and influences serves as an introduction to the subject, in which the continuous operation of geographical conditions on man is shown, and their importance in the history of peoples is emphasised. These influences are classified into the physical effects of environment; the psychical effects, which are bound up in many physiological modifications, and help to differentiate peoples and races in point of temperament; the economic and social effects; and, lastly, the influence of the features of the earth's surface in directing the movements and the ultimate distribution of mankind. From this general statement of the scope of the subject illustrated by numerous instances from the history of peoples of all stages of development we pass to the results of environment as seen in general location; here the relations of a society or state to the land come first, since in geography a human group is not conceivable apart from the land on which it dwells.

Such considerations lead naturally to the more definite treatment of the geographical significance of environment in the bearings of geographical location, the influence of geographical area on its inhabitants, and the various types of geographical boundaries which exist. The examples which support and illustrate the treatment of these subjects are drawn from primitive races, semi-civilised peoples, and the civilised nations, from the races of the past as well as of the present, so as to show the importance of taking into account the stage of culture and world-relations when drawing deductions from the facts of geographical environment. The aspects of specific location are next discussed, and the part played by seas and oceans, rivers and lakes, by continents and islands, plains and deserts, mountain barriers and their passes is explained as influencing the distribution, development, and movement of the peoples inhabiting them. The people of the coast, island races, and mountain tribes are thus investigated in order to show the effects which have been produced on them by their environment.

In this way and with the aid of a full bibliography at the end of each chapter a very large amount of information relating to the influence of the earth's surface on its population has been collected and presented in a very convenient form. Definitions and systematic classification have been avoided intentionally from the conviction that the subject is being but gradually evolved, and has not yet reached a stage at which such can be usefully introduced, but some provisional efforts in this direction would have assisted the geographer who avails himself of the mass of material here provided and the original works to which he is referred. Precise description and quantitative treatment by recognised scientific method is much needed in this branch of geography, and Miss Semple has placed English-speaking geographers under a deep obligation by her scholarly treatment of the influences of geographical environment. It is for them now to carry forward the investigation into specific instances in order to determine the value of the different factors involved in each case, so that human geography may be as precise and definite in its methods and its results as the physical branch of the subject. To this end accurate and well-designed maps are of great assistance in representing the distribution of data, and we must regret that most of those in the present work are not satisfactory; the drawing is coarse and the scale is indicated by the lines of latitude and longitude only. Printed on suitable paper line blocks give excellent results, and looking at those which illustrate German text-books on this and other subjects, it is to be desired that they should be employed here to better advantage.

THE AMERICAN AND COUNTRY LIFE.

The Country-life Movement in the United States. By Prof. L. H. Bailey. Pp. xi+220. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 5*s.* 6*d.* net.

TO the untravelled Englishman, who still looks upon money-making and hustling as the natural habit of the American, the steady outflow of books from the United States dealing with the country and with country life comes as a great surprise. But those who have had the privilege of meeting the American in real life know that he, too, like the Englishman, has an inborn love of the country, which has not been killed off even by a couple of generations of town life, and is now asserting itself more than at any time in our previous history. Indeed, this

conscious love of country life so often (and sometimes so mawkishly) expressed, is perhaps one of the most significant of modern characteristics.

Two factors play a highly important part in the movement: the purely personal factor, a desire on the part of the individual to get away from the artificiality of the city into the green fields and the woods, and the social factor, a realisation that only by making the most of our natural resources and getting the greatest possible produce out of the land can the community be established on a sound basis. We may thus roughly divide the literature of the subject under two main headings. Several of Prof. Bailey's books deal with the second aspect of the problem; in the present he takes a complete survey of the whole field.

The country-life movement, he states, is the working out of the desire to make rural civilisation as effective and satisfying as any other civilisation. It is thus to be an end in itself, and not merely a way of raising more food, or of absorbing city undesirables, or increasing the price of land, although all these things may happen as secondary consequences. The Commission on Country Life appointed by President Roosevelt in 1908 was the first organised expression of the movement in the States, and it found that agriculture is not commercially as profitable as it is entitled to be, and that the social conditions of the open country are far short of their possibilities. Three great campaigns were recommended: a survey of rural resources; the organising of a nationalised extension work; and the inauguration of a general campaign of rural progress. All are, in Prof. Bailey's view, equally necessary; every rural community needs to have a programme of its own carefully worked out, and this programme should rest on a physical valuation. It is high time that this work was put in hand; much of the necessary information has been collected by the agricultural colleges, and in general men are available for carrying out these great constructive plans once they are evolved.

But some very clear thinking must first be done, and a good deal of confusion must be brushed away. Especially must we avoid one very common error—the idea that suburbanism and gardening constitute country life. It is to the development of the village, not as the suburb of a great city, but as the place where the inhabitants actually earn their livelihood, that Prof. Bailey looks for future progress. As a first step farming has to be made more profitable by eliminating non-effective charges (the middleman, according to Prof. Bailey, secures over 50 per cent. of the proceeds in some cases), and more power, political, social, and commercial, must be given to the village. Further, the village and city must not compete. "We can never again be a rural people. We want the cities to grow." But it is also necessary to impress upon the cities the fact that they stand to gain by having an efficient village society, a new social order evolved in the open country, to which every farmer must contribute his share. Whilst the tendency of the city is to make eight-hour men and clock watchers, this new society must aim higher, for its business is the struggle with nature and the conquest of the earth.

E. J. R.

ELEMENTARY METEOROLOGY.

Weather Science: an Elementary Introduction to Meteorology. By F. W. Henkel. Pp. 335. (London: T. Fisher Unwin, 1911.) Price 6s. net.

IN elementary text-books of meteorology it is the custom to begin with a description of the action of common instruments like the barometer and thermometer, and of common facts like the apparent motions of the sun, and to continue the theoretical development as far as elementary mechanics and thermodynamics. Exigencies of space prevent a complete exposition, and it is found necessary to omit explanations at some stages. Unfortunately, authors almost invariably choose the later stages for the omissions; there they give merely the bald statement of facts, with little or no explanation. It would seem desirable to omit certain introductory matters which can be found in all elementary text-books on physiography or physics, and to reserve the space for a fuller treatment of the special problems of the atmosphere. In the book before us, the author describes in detail the apparent motions of the sun, but assumes that his readers understand the term "latent heat," and gives no explanation of the effect of change of pressure on moist air.

Nevertheless, Mr. Henkel has produced an interesting and readable book. He has quoted freely from authorities such as Abercromby, Scott, Waldo, Maury, and Inwards, and has, in some cases, added paragraphs and chapters giving a description of more recent work. The additions are not all as complete as could be desired, and they usually appear to be culled from isolated books and papers, producing a somewhat fragmentary result in places. Thus, a reference is made to Simpson's new theory of thunderstorms as it appeared briefly in NATURE, but other new theories are not mentioned.

Perhaps the most serious criticism that would occur to a reader is the almost complete absence of diagrams, and more especially of charts and maps. The book is by no means free from illustrations, but they are almost entirely reserved for instruments and cloud forms, the latter being particularly good. We doubt whether a reader new to the subject would understand clearly the verbal descriptions of the distribution of mean pressure, air and sea temperatures, and ocean currents; and the explanations of Buys Ballot's Law and of the types of pressure distribution are incomplete without illustrative examples.

The author has allowed himself to build up a complete story under the general heading of each chapter, irrespective of whether a part of the story appears elsewhere in another connection. Thus, Buys Ballot's law is stated no less than three times in three different chapters. The reiteration of the fundamental law of dynamical meteorology has its advantages, but other repeated statements are open to question. Among these is one affirming that rain in mountainous districts is due to the cooling effect of the summits on the warm moist air passing over them. Meteorologists are not yet agreed as to whether a mountain peak is in general cooler than the surrounding air, but even allowing a considerable temperature difference,

the dynamical cooling due to the forced ascent of the air and consequent reduction of its pressure is a more effective rain-producing agent.

We have noted a few misprints and mis-statements, but in general the principles as stated are sound. The book is well printed on good paper, and there is a useful index; but the binding of the copy that we have has already given way.

R. C.

A GARDEN OF HERBS.

The Herb-Garden. By Frances A. Bardswell. Pp. viii+173+plates. (London: A. and C. Black, 1911.) Price 7*s.* 6*d.* net.

ONE of the most delightful charms of old English gardening must have been due to the numerous sweet-smelling and aromatic herbs that were commonly cultivated around the homesteads. The very earliest records of gardening were supplied us by the ancient herbalists who cultivated their simples for medicinal purposes or for the pretty sentiments and conceits that legend had associated with them, but there is sufficient evidence that the herbalists took pleasure in their plants for the further reason that many of them possessed the qualities of beauty and fragrance. As we read Gerarde and Parkinson or Culpepper, we seem to breathe the atmosphere of the herbalist's garden, laden as it was with the delightful perfumes of lavender, balm, rosemary, southernwood, and many other plants the names of which are scarcely known to modern gardeners, much less their distinctive qualities.

The comparative neglect of the herbs which fire the enthusiasm of the author may be traced to a feeling allied to contempt, directly due to the fact that modern medical science has exposed the fallacious character of the beliefs formerly entertained in respect to their healing qualities. The contempt was natural enough, although unscientific and illogical, as is the case with most things which are merely the results of reaction. We are only just beginning to realise that, even when it is admitted that the garden simples are not "heal-alls," yet they have a wonderful interest for those who care to study them and admit them to their gardens.

At this point Miss Bardswell's book comes to show how we may make the most of the herbs from the point of view of the decorative gardener. It convinces the reader that many of the species have claims which should entitle them to every consideration—fragrance, romance, and economic value in the kitchen, still-room, and nursery. The pictures by the Hon. Florence Amherst and Miss Forrest are a pretty feature of the volume, and they greatly assist the author in presenting her case, for they show that, if but few of the sweet herbs possess such brilliant flowers as, for example, the bergamot, nevertheless many of them are sufficiently decorative to provide charming subjects for the artist's brush. And what about their cultivation? The author gives all the information necessary for any novice who wishes to engage in their culture. There are directions for planting, propagation, harvesting, and drying, with other details. We have known many cases where herbs were given a prominent place in the garden, and every care expended on their cultivation, but they were not utilised indoors, as they might be, because there appeared to be a lack of knowledge as to the time proper for cutting them and the care they require until they are perfectly dry.

The first things to consider in the formation of a herb garden are what site to choose and what style to make the beds. The author has something to say on these matters, but she is not inclined to be rigid in her recommendations. Beyond insisting upon the necessity for sunshine, she does not lay down rules as to the form of beds, she pleads for the cultivation of the herbs and is content if they are planted in beds or in ordinary flower borders, remarking that one of the best collections of herbs she has seen was grown in a kitchen garden. For ourselves, the interest we have in the plants is partly for their fragrance but equally for the sentiment that belongs to them in the legends. Consequently we admire them most when they overlay the confined borders of the narrow and oblong beds in the old English garden, with paved paths on which the thyme and other low-growing species find homes in the soil between the flags, the whole surrounded with venerable walls supporting old-fashioned climbers, including the fragrant myrtle, honeysuckle, and other species reminiscent of a long-past age. Such a garden we saw quite recently in North Wales, where the lavender bushes were three feet high and as much through.

PHYSICAL CHEMISTRY FOR THE GEOLOGIST.

Vorlesungen über die chemische Gleichgewichtslehre und ihre Anwendung auf die Probleme der Mineralogie, Petrographie, und Geologie. By Prof. R. Marc. Pp. vi+212. (Jena: Gustav Fischer, 1911.) Price 5 marks.

IN this little volume Prof. Marc gives the substance of a course of lectures delivered at the University of Jena, dealing, as the title announces, with the theory of chemical equilibrium in its application to mineralogical and geological problems. We gather from the preface that these lectures were addressed to students not previously acquainted with the modern developments of physical chemistry. It is to be presumed that the material has undergone considerable condensation for the purpose of publication, for a student in this situation must read very closely if he is to obtain the full benefit of the book before us. He will be aided by the simplicity of the general plan, and by the author's clear method of presentation, while the numerous well-chosen references will enable him to pursue farther any particular part of the subject.

The first lecture treats of the general conception of chemical equilibrium, and the second introduces the reader to the law of mass action and the phase rule. The next two lectures deal with the conditions of equilibrium in systems of one component, the illustrations being drawn so far as possible from cases which are of importance to the geologist. Thus the dependence of melting-point on pressure is considered with special reference to the case of ice. Polymorphism

in the mineral kingdom is discussed, and a list of examples given, which might be considerably enlarged. Three lectures are devoted to two-component systems, introducing the subjects of solution and solid solution, and discussing the crystallisation of silicate-magmas of ideal binary composition. Next we come in due order to three-component systems, which are treated less fully than might be expected. The author makes a bold attempt to construct a diagram for the system silica-lime-magnesia by combining data drawn from various sources. He does not allude, except in a passing reference, to Schreinemaker's work. The important case of an aqueous solution containing several components receives due notice, and the results of van 't Hoff's researches on the crystallisation of marine salts are given at some length. A lecture on surface energy in its application to geological phenomena contains much interesting matter. Joly's work on sedimentation is not cited, but there is an account of Schade's curious researches on the oolitic structure. In the final lecture, dealing with cosmology and vulcanology, the author has permitted himself some latitude of speculation, and some of his remarks are at least open to debate.

The book will serve as a very useful guide to chemical geology. Its information is in general well up to date, though a few exceptions may be found; for instance, Shepherd and Rankin showed two years ago that the high-temperature form of silica is not tridymite but cristobalite.

A. H.

FEEBLE-MINDED CHILDREN.

(1) *The Feeble-minded: a Guide to Study and Practice.* By Dr. E. B. Sherlock. With an introductory note by Sir H. B. Donkin. Pp. xx+327. (London: Macmillan and Co., Ltd., 1911.) Price 8*s*. 6*d*. net.

(2) *Feeble-mindedness in Children of School Age.* By Dr. C. P. Lapage. With an appendix on Treatment and Training by Mary Dendy. Pp. xiv+359. (Manchester: University Press, 1911.) Price 5*s*. net.

THESE two books are in a sense complementary of one another, the former being a work which might easily be of interest to the general reader, and will certainly be a useful help to those who are engaged in the care of the feeble-minded, while the latter is essentially a scientific book in which idiocy and imbecility are treated from a more academic point of view. Both works take full advantage of the information obtained by the Royal Commission on the Care and Control of the Feeble-minded, which was appointed in 1904 and concluded its work in 1909.

(1) Dr. Sherlock's book has seventy pages devoted to a brief account of the nature of mind and its physical basis. The two chapters, though brief, give a very good working foundation for the study of mental deficiency. Then follow another sixty-four pages on the nature of the "feeble mind" and its physical basis, including discussions and illustrations of such conditions as microgyria, porencephaly, irregularity of the convolutions, &c. There is also a description of changes in the dura mater, skull cap and scalp and of the various deformities commonly known as the physical stigmata of degeneration.

The chapter on "Causation" is excellent and, *inter alia,* compresses into a short space all the chief views which have been held in modern times as to the nature of heredity.

Dr. Sherlock introduces a new classification of the varieties of idiocy which coincides for the most part with former classifications, but there are some new words which display his known tendency to eschew consonants from his neologisms. The "ateleiotic forms" are the "minds in miniature" without abnormal development of any one faculty, such as occurs in some idiots. The hypertrophic sclerosis of Bourneville receives the new name "epiloia" which includes the author's cases formerly comprised by his term "anoia." All the paralytic cases are grouped together under the name of "plegic forms" and there is a separate group of "residual forms" in which are included presumably all the rarest forms of idiocy. The author does not make any separate group for epileptic idiots inasmuch as he regards the occurrence of fits as accidental to all varieties of idiocy and insufficient to warrant a separate clinical group, however convenient for practical purposes.

The work concludes with a very clear chapter on the handling of the feeble-minded, the way in which they may be placed under care, legal relationships, mental and physical examination, mental and physical training, craftsmasters, craftsmistresses, &c.

(2) Dr. Lapage's book, so far as practical relationship of the feeble-minded is concerned, is based upon experience at the Sandlebridge Colony for the Feeble-minded, and there is an appendix by Miss Mary Dendy, honorary secretary of the Lancashire and Cheshire Society for the Permanent Care of the Feeble-minded, on the treatment and training of these patients.

Her chapter, in common with the rest of the book, is very well arranged under the headings of admissions, food, dress, dormitories, bath-rooms and lavatories, wardrobes, dining- and day-rooms, kitchen utensils, school, work, games, hospital and sick-rooms.

Naturally the treatment of the subject by Dr. Lapage falls under similar headings to those of Dr. Sherlock. There are chapters on the statistics of the subject, on the physical and mental characteristics of the patients, diagnosis and prognosis, &c.

Four chapters are devoted to the condition of the brain in feeble-mindedness and on its causation by inherited and acquired factors.

To the general practitioner an appendix giving a list of institutions for the mentally defective, including asylums, homes, colonies, and schools, will be found exceedingly useful, seeing that mental deficiency is so very common, and the provision for patients suffering therefrom so small and so little known. There is a very good chapter on the defects of speech.

From both the above books we learn that feeble-mindedness is an incurable condition and that the only hope for such patients lies in institution care. The patients can be trained to become useful in handiwork and capable of earning their own living,

but they are incapable of competition in the outside world, and require constant and skilled supervision. There is a large amount of accommodation for these patients, but, as already said, it is too small for the numbers to be found in this country. Those in charge of institutions for the feeble-minded will find a great deal of help in their management and treatment in the book by Dr. Lapage, and they will find considerable interest added to their work if they study these patients in a scientific spirit on the lines laid down by Dr. Sherlock.

ELEMENTARY MATHEMATICS.

(1) *A First Book of Geometry.* By J. V. H. Coates. Pp. xi+142. (London: Macmillan and Co., Ltd., 1911.) Price 1*s.* 6*d.*

(2) *A School Algebra.* Part ii. By H. S. Hall. Pp. vi+301–450+xxxix–l. (London: Macmillan and Co., Ltd., 1911.) Price 1*s.* 6*d.*

(3) *Theoretical Geometry for Beginners.* By C. H. Allcock. Revised and rearranged. Part i., pp. xii+125. Parts ii.–iv., pp. xii+204. (London: Macmillan and Co., Ltd., 1911.) Price, part i., 1*s.* 6*d.*; parts ii.–iv., 2*s.* 6*d.*

(4) *A New Trigonometry for Schools and Colleges.* By the Rev. J. B. Lock and J. M. Child. Pp. xii+488. (London: Macmillan and Co., Ltd., 1911.) Price 6*s.*

(5) *Solid Geometry.* By C. Godfrey, M.V.O., and A. W. Siddons. Pp. ix+109. (Cambridge University Press, 1911.) Price 1*s.* 6*d.*

(6) *Engineering Descriptive Geometry: a Treatise on Descriptive Geometry as the Basis of Mechanical Drawing, explaining Geometrically the Operations Customary in the Draughting Room.* By Commander F. W. Bartlett and Prof. T. W. Johnson. Pp. vii+159. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.)

(7) *Trigonometria Esférica.* By Prof. C. Wargny. Pp. 219. (Valparaiso: Talleres Tipograficos de la Armada, 1909.) Price 6 dollars.

(1) THE object of this small text-book is to give the reader a sound appreciation of the fundamental ideas of geometry, rather than a systematic knowledge of its theorems. Without doubt this is the best way of approaching the subject. As soon as an intelligent grasp is acquired of such concepts as angles, parallelism, areas, &c., it is a simple matter to take a theoretical course; but without this preliminary stage, not only is progress very slow, but the work is in itself of little educational value. Part i., which occupies one-quarter of the book, is entirely practical; part ii. contains a selection of the important theorems of Euclid, I., III., with a large quantity of numerical exercises; it is, in our opinion, unfortunate that few riders have been inserted.

(2) The second part of this book carries the reader up to the binomial theorem. A change from the customary order has been made by taking a first course of progressions immediately after quadratics. As is to be expected of so well known an author, the quality of the workmanship is excellent throughout. The explanations in the text are clear and concise, and the examples have evidently been selected with great care.

(3) In spite of the title of this book, which is a revised form of an older edition, practically no work on experimental geometry has been included. After an introduction of twelve pages on definitions, axioms, postulates, &c., the reader is at once immersed in the theoretical work. The course of theorems given agrees fairly closely with the Cambridge schedule, with a few additions. Each proposition or group of propositions is followed by a number of riders, of which only a few are numerical. We are unable to find any very novel or distinctive features in this text-book.

(4) This volume is designed for the use of candidates for scholarships at the universities, and is intended to form an introduction to the more advanced parts of Dr. Hobson's standard work on the subject. Although it assumes no previous knowledge of trigonometry, the earlier portions are scarcely sufficiently full for the novice in view of the modern idea of taking the subject at a very early stage in the school course. For introductory purposes, some such book as Mercer's "Trigonometry for Beginners" is more useful. But after this preliminary stage is covered, it is well for the student to revise this work once more in such a form as is provided by this text-book. Practical applications are fully treated, and there is an abundance of numerical and graphical work. One important change has been made in the sequence of subjects. The applications to the geometry of the triangle and quadrilateral have been deferred to the closing chapters, thus avoiding any break in the presentation of the purely analytical work. The sections on geometry are far fuller than usual, and indeed contain more than the ordinary boy is likely to require or be able to digest. This is, however, a matter for each individual teacher. We are glad to find a full treatment of the geometrical interpretation of imaginary quantities; the interest which the student takes in this kind of work and the stimulus it applies to his mind more than justify the expenditure of time involved. The general theory of infinite series and products is regarded as beyond the scope of the book, but sufficient is said to justify the validity of the use of those particular series and products met with in the course of the work. Hints for the solution of the more difficult questions are included among the answers.

(5) In spite of recent geometrical reforms, the attention paid to three-dimensional geometry is still, to say the least, inadequate. Time does not allow of a course on the lines of Euclid XI., nor would this be particularly beneficial. What is required is an informal study of the ideas and practical applications of solid geometry; and this is supplied in an excellent and brief form by the work before us. The authors have had a great deal of experience in this direction, and it is not therefore surprising that this small book should seem so admirably adapted to the purpose for which it is intended. It falls into three sections: (1) a discussion of the main properties of lines and planes; (2) the properties and mensuration of the principal solids; (3) the elements of practical solid geometry. The examples are chiefly numerical, but a sufficient

number of riders has been included to test the student's grasp of the theory.

(6) The treatment in this volume is practical rather than mathematical, and is designed for the use of those taking a course in mechanical drawing. Elementary in character, it provides a thorough introductory account of the subject. The first chapter considers in great detail the nature and meaning of orthographic projection, using three planes of reference. Next an account is given of the projection of a straight line and the method of obtaining the true length of a line in space. After this follow successively the treatment of the intersection of planes, curved lines, and surfaces, and the traces of lines and planes with various applications, and the book closes with a description of isometric projection. The excellence of the diagrams is a feature which calls for special remark. The explanations are clearly put, and the work is so arranged that no special mathematical ability is required.

(7) The absence of spherical trigonometry from the ordinary school syllabus is both surprising and unfortunate in view of the practical applications which may be made; nor can this omission be excused on the score of difficulty, since the analysis is scarcely more difficult than that of the corresponding work in plane trigonometry. The explanation, of course, lies in the fact that it is at present excluded from the schedule for university scholarships. The book before us contains in a rather unduly elaborate form the kind of course which might be incorporated in a school programme. After a preliminary discussion on spherical triangles, the methods for solving right-angled triangles are first explained, and then the general case of oblique-angled triangles is considered. Great care is taken to explain the best way of arranging the work in numerical examples. The concluding chapters of the book give applications to geometry, astronomy, and navigation. Theory is throughout subordinated to practice, and those who require a comprehensive working knowledge of the methods of this subject cannot do better than read through this book.

OUR BOOK SHELF.

L'Évolution de l'Électrochimie. By Prof. W. Ostwald. Translated by E. Philippi. Pp. 266. (Nouvelle Collection scientifique: directeur, Émile Borel.) (Paris: Félix Alcan, 1912.) Price 3.50 francs.

THE evolution of electrochemistry affords probably one of the most interesting chapters in the history of the progress of chemical knowledge. Since the birth of this branch of chemistry may be regarded as dating from the discovery of so-called voltaic electricity, the period covered by its history is limited to a little more than a century. The comparative shortness of this period has certain obvious advantages, and the many discoveries of fundamental importance made by investigators in the field of electrochemistry, as well as the development of theoretical knowledge relating to the nature of and connection between electrical and chemical energy afford particularly attractive material for an historical study.

The account presented by Prof. Ostwald, who may be legitimately regarded as the greatest authority on the subject, is admirable in every way, and a more fascinating description of the development of a branch of science cannot well be imagined. The subject-matter and mode of treatment is indicated sufficiently by the titles of the sections into which the text is divided, viz.: (1) introduction; (2) prehistory; (3) Galvani and Volta; (4) Ritter and Davy; (5) from Faraday and Daniell to Hittorf and Kohlrausch; (6) electromotive forces; (7) the beginning of technical electrochemistry; (8) van 't Hoff and Arrhenius; (9) the ionists; (10) modern electrochemical industry; (11) the electron. In this final chapter a very brief but well-written account is given of the results attained in the investigation of the conductivity and the ionisation of gases, which results have given so much impetus to the development of the electron theory.

Much of the material collected and condensed in this little volume is to be found in Ostwald's compendious treatise on "Elektrochemie," published in 1896. This book, largely on account of its size, is comparatively little known amongst students of physical chemistry, and the appearance of a smaller work is therefore in itself an event of some importance.

The Life and Love of the Insect. By J. H. Fabre. Translated by A. T. de Mattos. Pp. x+262. (London: A. and C. Black, 1911.) Price 5s. net.

SEVERAL translators have already drawn from the abundant well of Fabre's entomological studies, and the volume before us is a pleasant addition. We like the grateful tribute to the veteran which the preface pays, and the quotation from Maeterlinck in regard to this "Insects' Homer," "who is one of the most profound and inventive scholars and also one of the purest writers, and, I was going to add, one of the finest poets of the century that is just past."

The book tells us of the sacred scarabee supremely inspired by the instinct of maternity to wonderful industry and not less wonderful art; of the Spanish Copris which kneads a large loaf and divides it into pills, one for each egg; of the common dung-beetles (Geotrupes), who belong to the public health service, and are often deservedly decorated; of *Minotaurus typhaeus*, a black beetle of the sheep's pasturage, who burrows and bakes, and even makes sausages; of the ringed Calicurgus, which first stings its captured spider in the mouth, paralysing the poison fangs, and then, safe from being bitten, drives in its poisoned needle with perfect precision at the thinnest part of the spider's cuticle between the fourth pair of legs; of the leaf-rolling Rhynchites, which spends the whole day in making an inch-long cigar with eggs between the layers of the scroll; and of the mother of the Halictus bee family, who becomes in her old age the portress of the establishment, shutting the door with her bald head when strangers arrive, opening it by drawing aside when any member of the household appears on the scene. And so the stories run, full of dramatic situations and romantic interest. We know not which to admire the more, Fabre's style or his eyes. The translator has given us a fine rendering, which reads like the original.

(1) *Aids to Bacteriology.* By C. G. Moor and Wm. Partridge. Second edition. Pp. viii+240. (London: Baillière, Tindall, and Cox, 1911.) Price 3s. 6d. net. Paper, 3s.

(2) *Aids to Pathology.* By Dr. H. Campbell. Second edition. Pp. viii+228. (London: Baillière, Tindall, and Cox, 1911.) Price 3s. 6d. net.

THESE two little books contain a large amount of information in a small space. Neither professes to be more than an outline of the subject of which it treats, but both seem to be successful in their aim—that of acting as epitomes for the student and practitioner.

(1) The bacteriology treats of bacteriological methods, pathogenic bacteriology, and bacteriology as applied in hygiene in the examination of water, milk, foods, disinfectants, &c. A few slips need correcting—*e.g.* the statement that an antibody consists of two parts (p. 19)—and the Wassermann reaction needs amplifying somewhat; otherwise there is little to criticise, and some portions of the book are particularly good, *e.g.* the section on disinfectants.

(2) The pathology suffers somewhat from the attempt to include everything in so small a book—*e.g.* diseases of the teeth and parasitic worms—and other more important and fundamental processes are in consequence too briefly discussed. Fatty infiltration and degeneration are treated as though they are quite distinct. It is stated that active immunity is conferred by the injection of an anti-serum, whereas it is correctly stated a couple of lines later that this procedure confers a passive immunity. The diagrams indicating the interaction that occurs in the Wassermann reaction should render this subject clear.

R. T. H.

Senior Chemistry. By Dr. G. H. Bailey and H. W. Bausor. Pp. viii+509. Price 4*s.* 6*d.*
Senior Magnetism and Electricity. By Drs. R. H. Jude and J. Satterly. Pp. viii+446. Price 5*s.*
Senior Heat. By Drs. R. W. Stewart and J. Satterly. Pp. viii+300. Price 3*s.*
(London: W. B. Clive, University Tutorial Press, Ltd., 1911.)

ALL these books are based upon previous volumes issued by the same publishers. The first is an adaptation apparently of Dr. Bailey's "Chemistry for Matriculation," which was reviewed in our issue of May 11, 1911 (vol. lxxxvi., p. 345); the second of Dr. Jude's "Matriculation Magnetism and Electricity," noticed in these columns on June 23, 1910 (vol. lxxxiii., p. 485), and the third of the late Dr. Stewart's book on heat, noticed at the same time as the volume on magnetism and electricity referred to.

It would seem that the present volumes cover those parts of the respective subjects included in the syllabuses for candidates presenting themselves at the Senior Local Examinations conducted by the University of Cambridge.

Fifty Useful Metric Equivalent Tables. (London: The Central Translations Institute, n.d.) Price 6*d.* net.

PROVISION is made in these tables for the range of equivalents likely to arise in commercial dealings between this country and others using the metric system. The calculations are based upon figures supplied by the Board of Trade. The price equivalents deal with feet, yards, square feet, square yards, cubic feet, gallons, pounds avoirdupois, hundredweights, and forty cubic feet measurements—which are useful for checking freight charges. The prices are calculated at the rate of exchange of 25.22 francs to the £.

A Handbook of Physics and Chemistry. By H. E. Corbin and A. M. Stewart. Pp. viii+519. Fourth edition. (London: J. and A. Churchill, 1911.) Price 7*s.* 6*d.* net.

THE first edition of this book was reviewed in NATURE of January 4, 1900 (vol. lxi., p. 221). It will suffice to say that in its present form the volume covers the extended syllabus of work required for the first examination of the Conjoint Examining Board of the Royal Colleges of Physicians and Surgeons. Additional articles have been introduced in the present edition on hydrostatics, the polarisation of light, and Röntgen rays.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Electricity and Vegetation.

WITHOUT pretending to answer the question raised by Mr. Benham at the conclusion of his letter on p. 41 of NATURE of November 9, and without prejudging the results of recent experience on electrification of crops as reported on by Dr. Priestley and other impartial investigators, I would remind him and your readers generally that it is unsafe to attach a positive conclusion to a negative result obtained by supposed electrification of a wire network over a field, unless there is reasonable guarantee that such network was really kept positively electrified during considerable periods.

For instance, it has been attempted in the past, and it is still tempting, to supply electricity to a network by means of elevated spikes, arranged so as to utilise the gradient of potential naturally existing in the atmosphere. But think what singularly perfect insulation would be required to enable electricity slowly supplied in this way to accumulate until a fizzing point was reached. The attainment of such potential over a large area would in this climate be quite impracticable except when a thundercloud was passing overhead.

The same difficulty of adequate insulation must have militated against many attempts made in the past to supply electricity from artificial but old-fashioned high-potential sources, especially when the area to be supplied extended over many acres.

It must be further remembered that any metallic network not really charged, but kept practically at zero potential by leakage to earth, would be presumably detrimental to the growth of plants beneath it; inasmuch as it would tend to screen them from the natural inductive electrification to which they are entitled.

OLIVER LODGE.

Fish and Drought.

THE summer of the year 1911 will long be remembered for its excessive heat and dryness. These were especially trying to the inhabitants of streams and shallow lakes or ponds. I had the opportunity of studying a remarkable instance of this, which I think is worth recording.

The Château of Marchais, with its magnificent domain, the property of the Prince of Monaco, lies about 16 kilometres east of Laon, in the department of Aisne, and is well known as one of the best shooting estates in France. The sketch (Fig. 1) represents the park. It occupies a rectangle surrounded by a ditch or moat, A, B, C, D, consisting of four canals, each 1250 metres long and 16 metres wide, and carrying usually a depth of 1½ metres of water. These canals form a continuous sheet of water, 5 kilometres long, and there is a bridge, *a*, *b*, *c*, *d*, over each of them. The country, though well-wooded, is flat and peaty, and the level of the water in the ditch is that of the water in the ground all round it. Like the ground-water, it is subject to rise and fall according to the wetness or dryness of the season.

When I arrived on the morning of September 29, I observed that the ditch was quite dry, with the exception of the small tank or enclosure (*f*) for ducks at the lodge known as the Porte Rouge, where entry to the park is obtained over the bridge marked (*b*). Yet the water of the ditch is always full of fish, principally carp, tench, perch, and pike. Now there was nothing but dry mud. *With the water the fish had entirely disappeared, and without leaving a single dead one to mark where they had before abounded.*

On the evening of September 29 a violent storm of wind and rain broke, and it raged over the whole of northern Europe until October 1. I was curious to see the effect which this first important rain, which marked the breaking of the drought, would have on the ditch.

It is right to say that the full significance of the dryness of the ditch and the absence of dead fish had not sufficiently impressed me. I only felt that I was witnessing a

remarkable occurrence in nature and it excited my curiosity, but at first this curiosity went very little beyond considering how long it would take for the water to get back. With only this in my mind, I went round the park on the afternoon of September 30, when the weather had moderated a little, and I found that pools of water had begun to collect in places in the ditch, but I did not examine them, and I arrived at the conclusion that a little steady wet weather would soon fill the ditch up again.

On October 1 the weather was still very bad, but between the showers I took a walk along the margin of the ornamental water (*h*) on the west side of the château (*k*), which is connected with the south canal of the moat. A pool of water had collected here, and there was quite a quantity of small fish, not more than 10 or 12 centimetres in length, swimming about in the water, which did little more than cover its muddy bottom to a depth of at the most 4 or 5 centimetres, in which these small fish were able to swim. I noticed that the water was turbid and that the mud was

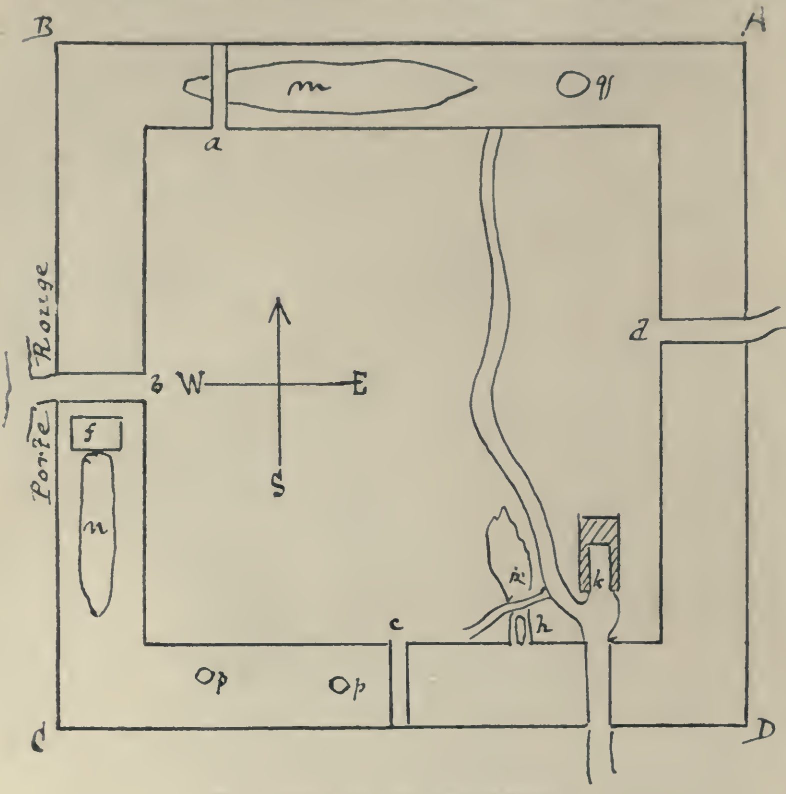

FIG. 1.—Sketch Plan of the Park of Marchais.

everywhere being stirred up by the fish. They were darting hither and thither, being disturbed by my presence on the bank, and, whenever they altered their course, they contrived to raise a dense cloud of mud, in which they were able for a short time to conceal themselves from view.

Two days before these fish were invisible, and now they had reappeared in an isolated shallow pool, which also had no existence two days before. *It was evident that all these fish had been covered by the dry mud, and must have released themselves the moment they thought there was enough water for them to swim in.* There was not by any means too much water for the crowd that was moving about in it. I was fascinated by what I saw, especially as it seemed to be in every way likely that the process of release was still going on. But the release of a buried fish would be sure to be accompanied by a cloud of mud, which could not be easily distinguished from that produced by a fish already in freedom and swimming about. Still, considering the shallowness of the water and the very favourable position for following everything that went on in it which I occupied on the bank, I was convinced that there would be some noticeable difference between the two classes of cloud, and I was not mistaken. After waiting and watching for some time, I saw a mud-cloud rise in the very shallow water, bringing a fish with it to the surface belly upwards. It lost no time in righting itself and swimming away with the others. A living fish can adopt this attitude only when it has not got full control over its movements, and this is pretty sure to be the case at the moment when it releases itself from burial. By waiting a little longer I witnessed two or three repetitions of this remarkable act.

In a pool such as that which I had under observation, in which the water was not more than two or three centimetres deep, the liberated fish reaches the surface almost as soon as it quits the bottom. In any case it is highly probable that the fish would arrive at the surface before it had fully seized the situation, and the nervous impulse had arrived at the muscles and started them in their righting and locomotive activity.

In water a very little deeper it is probable that the fish would be able to right itself before floating clear of the cloud of mud produced by its struggles in the act of self-exhumation.

In the afternoon I went round the park, and found an extensive pool of water which had collected in the north canal and occupied its western half. There were great shoals of fish, principally perch, darting about, and, in their alarm at being surprised in unusually shallow water, stirring up clouds of mud everywhere. Amongst them was one large pike, quite 40 centimetres in length. The water shoaled off to nothing at both ends of the pool, and in the middle it was perhaps 30 centimetres deep. The pool was far too long to be watched like the smaller one, and I was not able to observe any individual release from the mud. However, I noticed that, with the exception of the large pike, the fish were all small; I estimated them to be not more than 10 to 12 centimetres long.

From the western end of this pool round the north-west corner and along the western canal to the bridge (*b*), at the Porte Rouge, the canal was quite dry. At the Porte Rouge there was the small enclosed tank for ducks (*f*), and beyond it the canal was again dry. The bottom of this canal does not consist of the fine mud which is found in the north canal; it is hard, sandy, and marly, and there was no sign of life in it anywhere. The same class of bottom with absence of life prevailed in the south canal.

On October 2 the weather had improved, although it was very cold, and I studied the canals both in the morning and the afternoon. In the large pool in the north canal I found the quantity of fish augmented, and I especially noticed that there were many more large fish present than before, and the average size of the fish was decidedly greater than on the previous day; perch of at least 20 centimetres in length were present. The bigger fish had probably started to bury themselves earlier than the smaller ones, and had buried themselves deeper. I saw the big pike of the day before, and two others of the same species, but very much smaller, had appeared. *One dead perch was floating in the pool, the first dead fish that I had encountered.* In the afternoon it seemed to me that the average size of the fish in the pool was still on the increase. The west and north canals presented the same appearance as before.

On October 3 the weather kept fair but cold. I went round the park and found the big pool in the north canal much the same as on October 2, the number of large perch having apparently increased, but there was no new feature of importance. In the course of my tour, after passing the Porte Rouge, I found that the part of the west canal south of this lodge had begun to collect water, which already covered the bottom, forming a pool (*m*), extending to within a short distance of the south-west corner. Under the

water, which was perfectly clear, the light grey bottom was still cracked and apparently unsoftened, and there was not a trace of life of any kind. In the south canal the bottom was generally dry, with, however, every here and there pools of water measuring about one metre across, and in these also there was no trace of life. I learned that anglers never fish in these canals, because they know that they will catch nothing.

In the afternoon I revisited the north canal, and instead of following the big pool westwards, which promised nothing new, I turned to the right and followed it eastwards towards the north-east corner. I had not gone very far before I encountered a phenomenon of which I had already perceived the possibility, namely, *a premature resurrection resulting in widespread death.* This part of the canal was apparently dry, in the sense that the bottom was exposed to the air, but nevertheless moist enough to be called wet. Owing, probably, to a slight general rise of the ground-water of the neighbourhood, enough water had been able to filter through the mud of the bottom and to rise to the surface and overflow, producing a very shallow pool (*q*), not more than 2 or 3 centimetres deep or more than a metre across. The wetting of the mud below by this infiltration must have aroused the sleepers, who then all started to rise at the same time. But when they released themselves from the mud there was not enough water to float them all, and a formidable struggle for existence was going on at the time of my visit, and the quantity of dead and dying fish lying all round the edges of the pool furnished sufficient evidence of its fierceness. The poor fish would no doubt have willingly re-buried themselves and so saved their lives when they perceived their mistake, but the stronger ones, which were in possession of the only part of the pool which could be called liquid, kept shouldering them outwards on to the mud, where they died in the air. When I left the struggle was still going on, and it looked as if the level of the water was falling, so that it is unlikely that many, if any, would be able to retrieve their mistake by burying themselves again. As I left for England the next morning I was not able to continue my observations.

Although the years vary much as regards humidity, and in dry summers the supply of water in the ditch has often fallen to a pretty low ebb, I was informed that the last time that the ditch became quite dry was in the year 1814, almost a hundred years ago; therefore *the experience of the summer of* 1911 *must have been a new one for all the fish in the ditch, yet the general manœuvre of protective burial was carried out without a casualty.* In order to accomplish this a fine instinct was necessary to perceive the impending drying up of the canal, and then commence the operation betimes so as to finish it before desiccation was complete.

It must be remembered that the area of canal having the muddy bottom, which alone is capable of receiving them, is very restricted; and from the number of fish that came out of it in the short time that I was observing they must have been packed very closely, and in such an orderly way that, with the return of water in sufficient quantity, they were able to take to it again apparently without having suffered at all.

Although the instinct of the fish seems to have sufficed to make them foresee and provide for the dryness, it does not seem in all cases to have been sufficient to enable them to judge correctly the right moment for beginning their release.

Of the different species which inhabit the waters of the ditch, the carp and the tench have the habit of burying themselves in the mud every winter; but the perch and the pike have not this habit; both can be caught at any time in winter, even under a covering of ice; yet both the pike and the perch must have buried themselves with quite as much skill as the carp or the tench.

But in a climate like that of this part of France shallow lakes and ponds may suffer shortage of water by congelation as well as by evaporation; and the Prince informed me that he remembered one winter when in many places the water of the ditch was frozen almost, if not quite, to the bottom, and quantities of pike and perch were frozen into the ice. This form of desiccation did not prompt them to seek refuge in the mud.

It is evident that if the summer of 1911 had marked the beginning of a secular period of dryness, such that the canals were not again to be flooded, the fish which took to the mud in that summer would be kept there. They would die and decay *in situ*, and would be perfectly preserved in well-arranged though crowded masses. Eventually, if the change of climate was final, they would form a rich and interesting bed of fossil fishes. But the interest would depend not only on the abundance of fossils in the muddy matrix of one part of the trough-like formation; it would be intensified by their complete absence in the hardened marly matrix of the other part.

Before serious drying took place the ditch, or trough, was covered by a continuous sheet of water in which the fish and other creatures could circulate freely to all parts. So soon, however, as actual desiccation appeared to be imminent, the fish must have concentrated themselves in a body over the districts of muddy bottom in which they knew they could take refuge as a last resort. *When desiccation was complete every fish in the ditch, without a single exception, had succeeded in burying itself in one or other of these restricted areas of mud. Not one of them appears to have made the mistake of seeking refuge in the marly bottom.* When completely dry the ditch, or trough, consisted of two formations, the more extensive consisting of hard sandy marl and destitute of life, the less extensive consisting of soft mud and teeming with aquatic life. Further, the two formations are contiguous as well as contemporaneous, and together they cover an area of not more than eight hectares.

As illustrating the geological significance of the facts just recorded, the following passage may be quoted from Sir Archibald Geikie's "Text-book of Geology" (1903), p. 1003:—

"The water basins of the Old Red Sandstone might be supposed to have been, on the whole, singularly devoid of aquatic life, inasmuch as so large a proportion of the red sandy and marly strata is unfossiliferous. In some of the basins, where the sediment is not red and sandy, it is evident that life was extremely abundant, as is shown, for example, by the vast quantities of fossil fishes entombed in the grey bituminous flagstones of Caithness and Orkney. It may be observed that where grey shales occur intercalated among red sandstones and conglomerates they are often full of plant remains, and may contain also ichthyolites and other fossils which are usually absent from the coarser red sediments. There would appear to have been occasions of sudden and widespread destruction of fish life in the waters of the Old Red Sandstone, for platforms occur in which the remains are thickly crowded together, yet so entire that they could not have been transported from a distance, and must have been covered over with silt before they had time to decay and undergo much separation of their plates."

The last sentence of this passage seems to describe the actual condition of the muddy bed of the moat round the Park of Marchais as it would appear to a geologist after the necessary interval of time had elapsed which is required to separate the date of the death of the crowd of fishes which voluntarily entombed itself in the mud before desiccation was complete, and the date at which the stratum of mud and remains so produced would be entitled to rank as a geological formation. I do not know if there are any adequate data for arriving at a trustworthy estimation of the probable length of this interval. It is quite distinct from what is understood as the age of the geological formation.

The barren districts of sandy and marly matter at the bottom of the ditch would, after the lapse of the same, or perhaps a shorter, interval furnish perfectly unfossiliferous strata, which would suggest to the geologist of later date that the water basin in which it had been laid down had been singularly devoid of aquatic life. Yet, in a sense, it would not be inaccurate to say that the water basin in which the muddy strata holding the crowded fish remains had been "laid down" teemed with life, and that the barren strata had, in the same sense, been "laid down" in water devoid of aquatic life, although the two bodies of water formed one continuous sheet of very restricted dimensions. *It would seem, therefore, that a material barrier is not necessary to separate even a small body of*

water into two basins and to maintain them distinct, the one of which may be full of life and the other practically barren.

There is an important point, which should not be missed, in the similarity between what took place this summer at Marchais and what may have taken place in Caithness or Orkney in the Old Red Sandstone period. The fishes which buried themselves in such numbers in the mud this summer, though they were fortunately released, were in the strictest sense contemporaries, and were all buried in the mud within a few days of each other. Moreover, in ordinary circumstances, at least in summer, the mud is untenanted. If the fish were to migrate into the barren waters covering the marly bottom, and their return were barred while the water over the mud evaporated and the secular drought set in, this same mud-bed would be met with in later ages as an unfossiliferous stratum. *So that the fossil fishes which are found in these strata must be held to have gone into occupation only when the signal, intelligible to them, was made that complete desiccation was going to take place. Once in a way this desiccation turns out to be secular, and we have a rich bed of fossils.*

In conclusion, I think that the behaviour of the fish in the ditch at Marchais in the summer of 1911 adds one more fact to the body of evidence which goes to show that, *in the production of geological formations, transportation of material has probably been the exception rather than the rule.*

J. Y. BUCHANAN.

The Inheritance of Mental Characters.

I HAVE just read Dr. Archdall Reid's paper "Methods of Research," communicated to the Eugenics Education Society. Situated as I am in Scotland, it was impossible for me to attend the discussion which I understand took place recently, and I had no opportunity of reading his paper until he sent it to me. He makes certain statements with regard to a very controversial point, the inheritance of mental characters; and, having had no chance of criticising these, I should be much obliged if you would give me the opportunity of doing so.

Prof. Pearson, as quoted by Dr. Reid, says:—"We inherit our parents' tempers, our parents' consciousness, shyness, and ability, even as we inherit their stature, fore-arm, and span." This statement may be loosely expressed and open to misinterpretation; but no one has a right to assume, without further explanation, that more is meant than the inheritance of capacity or absence of capacity for making particular acquirements, whether Prof. Pearson actually had this idea in his mind when he wrote or not. At any rate, by ability he undoubtedly means capacity for making acquirements.

Dr. Reid says:—"Pearson's statement is utterly without significance, utterly devoid of all content. Founded with such an air of scientific accuracy on statistics and family histories which have such an appearance of scientific precision, it is so vague as to be quite nonsensical." This statement certainly does not err on the side of vagueness. If it is as true as it is definite it reduces the mental capacity of all men to that dead-level of competence or incompetence which is the apparent ideal of Socialists and trade unions; it necessitates the adoption of some other explanation than the action by selection upon the inborn variations for the evolution of man's capacity for making mental acquirements; and it leaves the undoubted existence of variations in mental capacity, including feeble-mindedness, unaccounted for.

Unless Dr. Reid believes that the intellectual development of man has been brought about by the action of some supernatural power or by the inheritance of acquired characters, he must believe that it has been due to the action of natural selection upon inborn variations. The term "mental character" is used by both Dr. Reid and Prof. Pearson in such a way that both inborn and acquired characters are included. The former classes the speaking of English, the latter temper, shyness, and ability, as mental characters. Many, perhaps most, of our mental characters, using the words in this loose sense, are acquirements; but these acquirements depend upon an inborn capacity for making them, and this capacity, like all inborn characters, is subject to variations. Without this it is difficult to see how man's capacity for making mental acquirements could ever have been evolved. Apply the method, which Dr. Reid supports so strongly and explains so clearly, to his own examples and those of Prof. Pearson! All normal English children speak English. All normal French children speak French. The particular language spoken is an acquirement, dependent upon the environment. But it is impossible for Dr. Reid to maintain that, given precisely the same opportunities, all individuals are likely to attain the same degree of skill in the use of the language they have acquired. Moreover, they will vary in the facility with which they acquire skill in the different ways of using the language. Some may readily acquire an abundant flow of words in speaking, others may more easily attain a facile and clear style in writing. Does Dr. Reid believe that a great English orator or writer would not, *ceteris paribus*, have been a great orator or writer simply because his medium happened to be French instead of English? This variability in the capacity for making acquirements must apply to all acquirements. An individual may be able to acquire a high degree of development in music under comparatively unfavourable conditions, but be quite incapable of rising, even to the average, in mathematics under favourable conditions, and *vice versa*. Unless the existence of these variations in mental capacity and the possibility of their transmission from parents to offspring are admitted, it is impossible to account for the evolution of the human intellect by the action of natural selection upon inborn variations.

Now take Prof. Pearson's first example, as quoted by Dr. Reid—temper! I do not think that anyone will quarrel with the postulate that this word is used to express the control, or lack of control, over the emotions exhibited by an individual, the strength of the emotion being a variable quantity according to the susceptibility of the individual to the stimulus producing the emotion. This susceptibility will vary just as grocers' scales vary from a delicate chemical balance, though both respond in a similar manner to the same kind of stimulus. "Good-tempered" implies the possession of a high degree of control or a low degree of susceptibility, or a combination of both. "Bad-tempered" means a lack of control or a great susceptibility, or a combination of both. Dr. Reid might contend that the example of a bad-tempered parent might produce a bad temper in the child. On the other hand, it is at least equally probable that the exhibition of bad temper on the part of a child to a bad-tempered parent would bring swifter and greater punishment than would have been the case had the parent been good-tempered; and thus the bad temper in the child would be more than usually checked. In the absence of direct evidence of a comprehensive and conclusive nature we must assume, given identical environment, that the susceptibility to stimuli tending to produce manifestations of temper is different in different individuals, and is an inborn character; that the capacity for acquiring control over the emotions varies in different individuals, and is an inborn character; and that these variations are transmitted in an increased or lessened degree to their offspring by the parents. These inborn characters are, of course, susceptible to great modification by the environment.

Using, I believe, methods approved by Dr. Reid, I have thus come to the same conclusion that Prof. Pearson has arrived at by a different road, and hold that mental characters are transmitted from parents to offspring, though I fully realise the great extent to which these inborn characters may subsequently be masked by superimposed acquirements. If this conclusion be correct, then the consideration of the inborn mental characters of the parents is even more important, from the eugenic point of view, than that of the inborn physical characters, and far more serious than any question relating to education.

What has surprised me is that on all previous occasions Dr. Reid's opinions seem to have been in complete accord with the arguments put forward here. Hence I do not understand his unqualified condemnation of a statement which does not appear, on the face of it, to be at variance with his own views.

CHARLES WALKER.

Glasgow, October 12.

Nature of Light Emitted by Fireflies.

THE nature of the light emitted by fireflies (Malacoder-nidæ fam., genus Luciola) has hitherto been very little nvestigated. The idea that it is phosphorescent seems to ave been generally accepted. On observing the beautiful reen fluorescence of the light emitted by the insect when t is put in a glass tube, we were struck by the close esemblance of this light to that of the Crookes's tube. Could it be like that of the X-rays?

An inquiry was instituted to see how it affects photo-graphic plates through different media. Various media vere tried, and the results obtained by interposing wood, lark brown leather, flesh, and black paper are described elow. It may be remarked here that the light emitted by he insect is so fitful and faint that it is rather difficult to keep it steady, and it will be too much to expect this faint ight to give more than shades of varying depth on the plates. It was observed that the capacity of the insect to affect the photographic plate depends on the length of the exposure. When the insect was put on a naked plate for a few seconds, it did not affect the plate, but when it was similarly held on the plate for one minute, its effect was distinctly visible. After a series of experiments, therefore, two hours' exposure in the case of paper and flesh, and three hours' exposure in the case of leather and wood, were considered sufficient.

(1) An extra rapid photographic plate was placed in a dark slide, and three insects were then placed on the slide beneath a watch glass; the whole plate was affected and gave dark grey print after an exposure of three hours. Without the insect, the plate gave a black print on a two minutes' exposure to lamp-light.

(2) An extra rapid photographic plate was enclosed in English tanned leather of a dark brown colour 1 mm. thick. The three insects were placed on the leather, with the result that the plate gave a dark grey print after three hours' exposure; a similar plate, similarly enclosed, when exposed to lamp-light for two minutes gave a black print

(3) The three insects were placed in a small tube open at one end, which was enclosed in a piece of flesh (mutton) 1·5 mm. thick; this was placed on a naked plate in a dark room. Where the light was not intercepted by the glass of the tube, the plate showed a white print after an exposure of two hours. A similar plate was covered with a piece of flesh of similar thickness and exposed to lamp-light; the resulting print was dark grey after two minutes' exposure.

(4) A similar plate was enclosed in black paper and the insects placed on it beneath a watch glass; the resulting print was, after two hours' exposure, light grey; while a plate similarly covered exposed to lamp-light for two minutes was very slightly affected, and gave a very dark grey print. The plate exposed to lamp-light without any media for two minutes gave a light grey print.

It was seen that the insect light approaches lamp-light in the intensity of its effect on the photographic plate, even when the different media opaque to light are interposed between the two.

The light emitted by the insect cannot therefore be taken as phosphorescent. It may be, perhaps, premature to conclude that some of the rays emitted by the insect are X-rays, but it may be safely asserted that these rays are, at least, similar to X-rays and ultra-violet light in so far as they render certain opaque media transparent and are intercepted by glass. We hope this short note may be the precursor of elaborate experiments on the subject leading to some definite results.

Trematode Generic Names Proposed for the "Official List of Zoological Names."

(1) THE International Commission on Medical Zoology, appointed by the Graz International Zoological Congress, has made its first report on the names of Trematode genera parasitic in man.

(2) Four members, namely, Blanchard (Paris), Monticelli (Naples), Stiles (Washington), and Zschokke (Basel), unanimously agree that the following eleven names are, from the present point of view of systematic zoology and nomenclature, the correct names for the genera in question, and that the species cited as genotypes are the correct types according to the International Rules of Zoological Nomenclature:—

Clonorchis Looss, 1907, February 1, 147–152, type *sinensis*.

Dicrocoelium Dujardin, 1845a, 391, type *lanceatum* = *lanceolatum* (= ? *dendriticum* sub judice).

Fasciola Linnæus, 1758a, 644, 648–649, type *hepatica*.

Fasciolopsis Looss, 1899b, 557, 561, type *buskii* (seu *buski* teste Blanchard).

Gastrodiscus Leuckart in Cobbold, 1877e, 233–239, type *sonsinoii* (seu *sonsinoi* teste Blanchard).

Heterophyes Cobbold, 1866a, 6, type *aegyptiaca* = *heterophyes*.

Metorchis Looss, 1899b, 564–566, type *albidus*.

Opisthorchis Blanchard, 1895f, 217, type *felineus*.

Paragonimus Braun, 1899g, 492, type *westermanii* (seu *westermanni* teste Blanchard).

Pseudamphistomum Luehe, 1908, 428–436, type *truncatum*.

Watsonius Stiles and Goldberger, 1910, 212, type *watsoni*.

(3) The following commissioners have not voted:— Jaegerskioeld (Gothenburg), Looss (Cairo), Luehe (Koenigsberg), Pintner (Vienna), and Shipley (Cambridge).

(4) Notice is hereby given that the undersigned will wait until July 1, 1912, for any zoologist to raise any objection to any portion of this report, and that on that date all names to which valid objection is not raised will be forwarded to the International Commission on Zoological Nomenclature with the motion that these names be included in the "Official List of Zoological Names" provided for by the Graz Zoological Congress.

(5) All correspondence on this subject should be addressed to the undersigned.

C. W. STILES.
(Secretary International Commission on Zoological Nomenclature.)

Hygienic Laboratory, Washington, D.C., November 11.

Dews in 1911.

IT may interest readers of NATURE to know that between July 31 and September 5 this year I collected a total amount of dew equivalent to one-fifth of an inch of water, whilst in 1909, between August 3 and September 12, about one-tenth of an inch was collected. That is to say that this year the dews were twice as heavy as in 1909, or we may state that during the above-mentioned period of this year the deposit of dew in my instrument was equivalent to 20 tons of water per acre. Of course, most of this was evaporated, but that amount of water could have been collected with adequate means.

This year has been disastrous to the so-called dew-ponds, and I would remind readers of the view expressed in a letter to NATURE of May 14, 1908, that the ponds are "simply water butts in which rain-water is stored." A pond on the summit of St. Boniface Down, Ventnor, which I visited on September 1 this year, was absolutely dry.

I have been led to write this note because Mr. Martin, in his interesting letter in last week's NATURE, p. 77, says that "this year the absence of rain for so long brought about a remarkable absence of dew." This was not my experience, except on two or three clear nights when the air seemed to be very dry.

The details of my measurements and of my instrument I hope to publish elsewhere.

SIDNEY SKINNER.

The Colours of Fishes.

INTEREST as to the sources of colours in birds and insects has been revived by Prof. Michelson in *The Philosophical Magazine* for April, and by Mr. Mallock at the Royal Society. The inquiry will be assisted if fishes may also be included. Nature reveals no more vivid form of shifting tints than we see in the common mackerel, which is a fish without scales. In August I was able to watch them immediately after the fish had been taken from the sea I

was surprised to find the skin so firm and tough; I almost expected to spoil it in handling; the delicate colours seem as if they might be tender like the bloom of a grape. With the smooth, but not sharp, edge of a knife I scraped the surface somewhat vigorously without damaging the lovely play of blue and green light.

Two or three weeks elapsed before I could examine dried pieces of the skin with a microscope. There did not appear to be any orderly markings which could lead to diffraction; nor could I find a flaking tendency which would suggest thin plates. The glancing of the colours from blue to green is lively, but I should think it is not due to wave interference. Pigments can be greatly modified by a change in the angle of incident light, according to the qualities of lustre surfaces as described by Helmholtz, and the polarisation principles worked out by Jamin. These two considerations form the basis of an important portion of the comprehensive discussion given by Michelson. W. B. CROFT.

Winchester College, November 13.

The Weather of 1911.

WITH reference to Sir Edward Fry's letter in NATURE of November 16 in regard to the weather of 1911, without presuming to reply on behalf of meteorologists to his question as to whether any real cause can be assigned for the brilliance and heat of its summer and autumn, may I be allowed to suggest that the relatively high temperature of the North Atlantic, during the period, presumably conduced to warmth and sunshine? Since April the surface temperature of the North Atlantic has been, for the most part, above the average, and during the months of June to September, inclusive, largely above. Not only through the agency of winds from seaward has air temperature over our islands been raised by the abnormal warmth of the ocean, but also, it seems probable, through the diminution of cloudiness, and the corresponding increase of sunshine attributable to the small difference, thus ensuing between the temperature of the sea and that of the air above it.

Moreover, during a bright summer, the heat which the earth receives through solar radiation may be greatly in excess of that which it parts with at night by terrestrial radiation. CAMPBELL HEPWORTH.

2 Amherst Road, Ealing, W., November 18.

ROTATION PERIOD OF THE SUN.[1]

SINCE the introduction of the Doppler-Fizeau principle one of its most interesting and important applications has been to the determination of the velocity of the sun's rotation by the investigation of shifts of the spectrum lines corresponding to various points on the solar limb. Much of the pioneer work in this direction was done by Vogel, Young, Langley, Cornu, and Dunér, the results obtained by the latter at Upsala from 1888 to 1903 serving as the standard for future workers. Dunér's determinations referred to points between the solar equator and 75° north and south heliographic latitude, the observations being made at intervals of 15°. During 1903–6 Halm made a series of observations at Edinburgh, employing the same differential method as Dunér.

All these observations having been made by visual methods, it was considered of importance that the photographic method should be tried, and this was commenced on the completion of the Snow telescope on Mount Wilson in the spring of 1906. In June, 1907, the tower telescope, with vertical spectrograph of 30 feet focal length, was completed, and thenceforward the observations for rotation were made with it, the spectra being of such greatly increased resolving power that the investigation was considerably facilitated.

[1] "An Investigation of the Rotation Period of the Sun by Spectroscopic Methods." By W. S. Adams and J. S. Lasby. Washington D.C., Papers of the Mount Wilson Solar Observatory. Vol. i., part i. (The Carnegie Institution, 1911.)

Five series of observations have been made—tw dealing with lines selected from the spectrum of th general reversing layer, two with the Hα line o hydrogen, and the fifth with the blue line of calciu at λ 4227. As the lines of hydrogen and calcium giv results differing widely from those obtained for th reversing layer, the various sections are treat separately in the discussion.

The 1906–7 series of observations were made in co junction with the Snow telescope, having a spectru scale of 1 mm. = 0·71A, on a list of lines selected being representative of the different strata involv Those made in 1908, with the tower telescope an spectrograph of 30-feet focal length, are with a spe trum scale of 1 mm. = 0·56A. For the reversing lay photographs twenty-two standard solar lines wer selected for observation, representing the elements La Cr, Zr, Fe, Mn, Ni, Ti, and the compound CN.

In the general discussion it is shown that the tw series of observations are in substantial agreemen for latitudes between 0° and 50°. Above 50° th

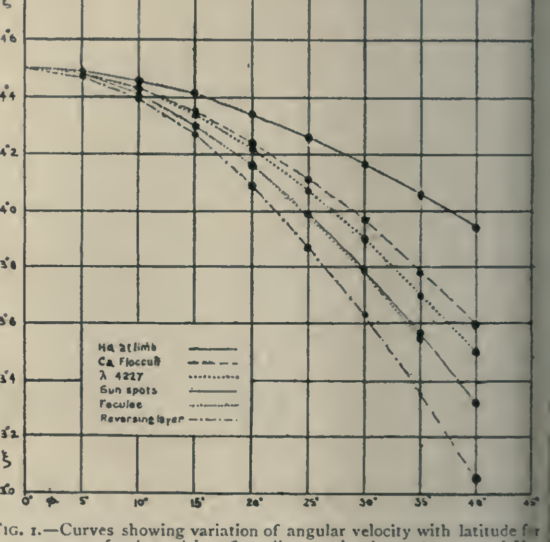

FIG. 1.—Curves showing variation of angular velocity with latitude for sun-spots, faculæ, calcium flocculi, reversing layer, λ 4227, and Hα. To facilitate comparison the curves are all reduced to the common origin of 14·50°. Differences in the amount of equatorial acceleration are indicated by lack of parallelism in the curves.

1908 observations give slightly smaller values, th greatest difference being about 0·039 km. at 70°. I is surmised that these small differences may be partl due to small systematic errors in the earlier series and partly to actual proper motions in the vapour constituting the sun's reversing layer.

The general results do not indicate any definit variation of the sun's rate of rotation, except it be c long period. This conclusion is emphasised by th close agreement of the Mount Wilson results wit those given by Dunér.

One of the most notable results brought out clearl by these observations is the fact that the lines c different elements give different values of the rotatio velocity. Thus lines of lanthanum and cyanogen giv low velocities, while certain lines of manganese an iron give comparatively high velocities. A table i given showing the residuals on forming the difference in the values of the angular velocity for each line fror that of the mean of all the lines. The systemati variation is at once rendered evident by the marke preponderance of positive or negative residuals. Th results corresponding to the different elements are, o

closer examination, found to be in close agreement with other evidence we have about the differences of level in the solar atmosphere. Lanthanum and cyanogen are usually regarded as low-level constituents, and they are also conspicuous in the present instance in showing consistently low velocities for the solar rotation. This indicates that the period of rotation increases as we approach the surface, or that the outer layers of the atmosphere rotate much more rapidly than those lying close to the photosphere. These facts are in good accordance with the results obtained for hydrogen and the other substances which are characteristic of high levels above the photosphere.

All the observations may be well represented by a slight modification of the Faye formula, showing that it may be applied with great accuracy to determinations of the sun's rotational velocity to within 10° of the pole. The adopted formula for representing the Mount Wilson observations is—

$$\xi = 11{\cdot}04^\circ + 3{\cdot}50^\circ \cos^2 \phi,$$

where ξ is the daily angular velocity, and ϕ the solar latitude. In this connection it is of interest to review

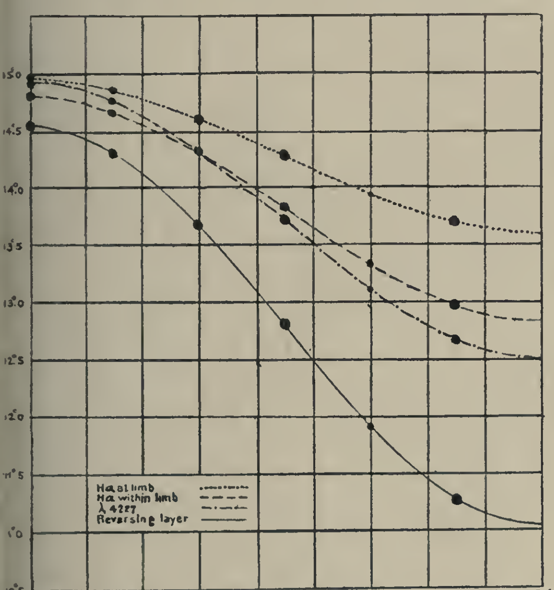

FIG. 2.—Curves representing the values of the angular velocity given by the empirical formulæ derived from the observations of Hα, λ 4227, and the reversing layer. For the last named the mean of the two series of observations is used.

the values of this equation which have been given by some of the more important determinations of the solar rotation made during the last century.

Observer	
Carrington	$\xi = 14{\cdot}42 - 2{\cdot}75 \sin 7/4\, \phi$.
Spoerer	$\xi = 8{\cdot}55 + 5{\cdot}80 \cos \phi$.
Maunder	$\xi = 12{\cdot}43 + 2{\cdot}01 \cos^2 \phi$.
Dunér	$\xi = 10{\cdot}60 + 4{\cdot}21 \cos^2 \phi$.
Halm	$\xi + 12{\cdot}03 + 2{\cdot}50 \cos^2 \phi$.
Adams (mean of two series)..	$\xi = 11{\cdot}04 + 3{\cdot}50 \cos^2 \phi$.
Adams λ 4226	$\xi = 12{\cdot}5 + 2{\cdot}4 \cos^2 \phi$.
Adams Hα	$\xi = 13{\cdot}6 + 1{\cdot}4 \cos^2 \phi$.

It will be noticed that both λ 4227 (calcium) and Hα (hydrogen) give considerably higher rotational velocities than the general elements of the reversing layer. The equatorial acceleration is considerably greater for λ 4227 than for Hα at the limb. The discussion of the numerous results is made much clearer by several diagrams; two of these are here reproduced, showing the main features outlined in this necessarily brief summary of a very extensive investigation. A word of caution is given as to the interpretation of certain results shown by the tables. Thus if the lines showing systematic large or small values of the angular velocity are specially considered, it is seen that there is an apparent increase towards the sun's pole. Comparison of the results found for sun-spots, faculæ, and the calcium flocculi gives the following sequence in order of *decreasing* equatorial acceleration: (1) spots and faculæ, (2) λ 4227, (3) calcium flocculi, (4) Hα. The reversing layer shows a greater amount of equatorial acceleration than any of these.

CHARLES P. BUTLER.

MAGNETIC OBSERVATIONS AT THE COLABA OBSERVATORY.[1]

THE two somewhat formidable volumes referred to below contain a most valuable compilation of observations extending over sixty years, together with a discussion of the results presented in a form in which they can be used in further investigations. Observations on terrestrial magnetism were started at the Colaba Observatory, Bombay, in 1840, but it was not until the year 1846 that regular records were obtained. When it was found that disturbances were likely to be caused by the electric traction which was being introduced in Bombay, it was decided to move the observatory to a more suitable site at Alibág, about eighteen miles away; and after securing duplicate records at the two stations in 1904 and 1905, the magnetic work at Colaba was finally abandoned in 1906. The first volume, extending over 264 pages, contains a complete description of the instruments and processes of reduction. The methods employed are described in great detail—some may think, perhaps, with too great diffuseness—but many interesting points are brought out incidentally. The complete record, for instance, of the monthly values of the magnetic moment of one of the standard magnets, extending over nearly forty years, is probably unique. This magnet does not show any tendency to approach a steady state: it is rather the annual diminution amounting to about the thousandth part of its value which has become steady.

Great attention is deservedly given to the temperature corrections. These were originally determined by means of thermometers suspended on the wall of the magnetometer room, and the corrections were obtained by assuming that the magnets had the same temperature as the walls. This—as is now found—has led to errors. A remarkable discrepancy between the diurnal variation deduced from eye observations taken above ground, and that deduced from the photographic records taken in the magnetometer room, led Mr. Chambers to suggest that the amplitude of the variation might be different according as the magnetometer is placed above or below the surface of the ground. Since the observatory was dismantled Mr. Moos has made a careful comparison of the temperature variations observed by the thermometers on the walls with those recorded by thermometers placed in the exact position of the original magnets, and found —as might have been expected—that the variations here were smaller. Rectifying the previously applied temperature corrections, it was found that the diurnal variations as observed in the two positions became identical.

1 "Magnetic Observations made at the Government Observatory, Bombay, for the Period 1846 to 1905, and their Discussion." By N. A. F. Moos. Part i., Magnetic Data and Instruments. Pp. v+263+plates. Part ii., The Phenomenon and its Discussion. Pp. xiv+vii+iv+265–782+plates. (Bombay: Government Central Press, 1910.)

In part ii. the results are discussed. After a detailed account of the secular and annular variations, the diurnal variations are examined from all possible points of view. The Fourier coefficients are calculated, and the differences between quiet days and the average values for all days are examined. An interesting chapter deals with magnetic disturbances and their effects on the periodic changes; the results obtained seem to be in agreement with those noted in other places. When the curves of different localities are compared, Mr. Moos finds that the progression of an average disturbance appears to be made up of a common pulse which commences everywhere simultaneously, a further change taking about ten or eleven hours to reach its maximum, and finally an accentuated diurnal wave. This last point is of some importance.

The special discussion of quiet days brings out the result that the absolute value of the horizontal force is higher, but that the annual variation is practically the same whether derived from these quiet days or from all days. It is interesting to find that when the quiet days are selected with reference to the magnetic state of the whole earth, the results differ less from the average of all days than when the quiet days are selected by purely local conditions. This result may prove to be of considerable significance to anyone seeking an explanation of the after-effects of a magnetic disturbance, for it seems to show that these after-effects are confined to those parts of the earth which have been affected by the storm.

Special attention must be directed to the chapter which deals with lunar effects. The influence of the moon on terrestrial magnetism—which undoubtedly exists—may either be an atmospheric effect or be due to the tidal distortion of the earth. It is of the highest importance to decide which it is, and for this purpose it is necessary to obtain the lunar variations at a number of different stations. Mr. Moos has done his share of the work for Bombay, but there are too few observatories which give sufficient data to allow a general discussion of lunar effects. The last two chapters deal with the connection of terrestrial magnetism with solar spots and its relation to meteorological and seismic phenomena.

Mr. Moos deserves the highest credit for having undertaken a work of such enormous labour as the preparation of these two volumes must have involved. We have only two criticisms to make. Some credit should have been given to the earlier observers, to whom the observatory of Colaba owes, in the first instance, its deservedly high reputation. Reference ought, for instance, to have been made to the volume published in 1872 by Mr. Charles Chambers, whose name only occurs in connection with a paper on the lunar effect published in the Philosophical Transactions. The second criticism may seem trivial, but is provoked by an unnecessary amount of trouble caused to the reader who looks at the laudably complete table of contents only to find that the references (in the second volume) are all to paragraphs and not to pages. Some of these paragraphs cover a great number of pages, and much irritation is caused by the time spent in turning over page after page until the right paragraph is found. The references should either have been made to pages, or the number of the paragraph should have been printed at the top of every page.

The two volumes, even with their minor faults of diffuseness and occasional obscurities of expression, form a most valuable book of reference, which no doubt will be extensively used by everyone wishing to obtain an insight into the complicated phenomena of terrestrial magnetism.

AGRICULTURAL EDUCATION IN THE UNIVERSITY AND THE SCHOOL.[1]

WHEN the council of the Reading University College decided to develop their agricultural department, they very wisely began by taking stock of the situation, and in view of the report of the departmental committee appointed by the Board of Agriculture to investigate agricultural education in England and Wales, they decided to go abroad for information. For the report confesses that the majority of English farmers are not reached by the agricultural colleges at all; indeed, one witness went so far as to assert that not more than 5 per cent. of the farmers of England are directly affected by them.

Agricultural colleges have, however, gained the confidence of the farmers of Canada and the United States. A deputation appointed by the college therefore visited the Macdonald College, St. Anne de Bellevue; the Central Experimental Farm, Ottawa; the Ontario Agricultural College, Guelph; and the Cornell and Wisconsin Universities in the States, to discover what features these institutions possess that enable them to gain the confidence of the farmer. At all the institutions the question of rural life as a whole is frankly dealt with, and women's courses, as well as men's, are arranged. Taking as a good example the Guelph College: there is a woman's institute where a complete training for rural life is afforded to women; there are altogether thirteen hundred men and women students, a third of whom are taking the full diploma or degree course; and there is so great a bond between the college and the farmer that during June, 1910, more than 40,000 agriculturists visited, or were expected to visit, the plots and demonstrations. In 1909, the college conducted definite experimental work on nearly 5,000 farms. Further, the college has about eleven official missionaries in the province: graduates who are sent out to gain the confidence of the farmer, to advise where possible on agricultural matters, and, above all, to bring the farmer into touch with the college. But the college is only part of a larger scheme. The Government of Ontario has a definite agricultural policy briefly set out in the report, into which we need not enter, except to note that the college is the centre for teaching, experiment, and constructive ideas. "From Guelph go forth to the country the trained farmer, the trained rural teacher, and the trained housewife." The college, however, is in no bondage to its official position, nor does its connection with the University of Toronto give it any airs of superiority or cold academic aloofness; it is closely in touch with its province by countless personal ties and shows a lively and vigorous sense of its responsibility.

With local modifications the same remarks apply to all the other colleges visited. In all cases the college is the centre of agricultural life for its district, and its staff is primarily concerned with the improvement of the local rural life.

Why is it that the Canadian and American colleges have succeeded so well, whilst the English colleges, whatever else they have achieved, have certainly not become the centre of rural life in the country? Partly, the deputation consider, because the English farmer is already highly competent and can only be helped by very able specialists. He has behind him a long tradition, and need look to no one for advice; in Canada and the States, on the other hand, the farmer has usually no tradition and must perforce turn to

[1] Agricultural Education: Report of a Deputation appointed by the Council of University College, Reading, to visit selected centres of Agricultural Education and Research in Canada and in the United States.
Memorandum on the Principles and Methods of Rural Education. (Board of Education, 1911.)

some honest, disinterested source for information; naturally he goes to the college. In England matters have sometimes been made worse by the appointment of rather poor agricultural instructors and by the fact that education is associated in the farmer's mind with heavy county rates.

Thus the success of the Canadian and American colleges, as compared with that of the English colleges, is partly to be attributed to differences in local conditions, and the deputation failed to discover a system that they could transplant here with any hope of success. They learnt much, however, and they applied the experience gained to their own problem at Reading and drew up a scheme for a complete agricultural department. Into the details of the scheme we need not enter; the principles on which it is based, however, seem to us to be very sound. First and foremost they consider that the staff must be competent. "In making any new appointment of major rank it is impossible to exaggerate the importance of securing a first-class man. . . . No proposition receives more lip-homage in educational circles, and perhaps none is more frequently flouted in practice." That a university agricultural department staffed in this way would be eminently successful is beyond dispute, and all interested in agricultural education will hope that Reading will have the means and the courage to go ahead. For as the deputation found out, specialisation is very necessary in agricultural work; indeed, they might have quoted the precisely parallel case of medicine. No college would think of setting up a professor of medical knowledge and one or two assistants as a medical school. Yet most colleges think the arrangement does sufficiently well for agriculture; only one agricultural department has more than one professorship; indeed, at one of our oldest universities even the examinerships are not specialised, one and the same person being required to examine both in agricultural botany and agricultural chemistry!

Passing now to the memorandum on the principles and methods of rural education issued by the Board of Education, it is quite evident that a serious effort is being made to bring the education of the country school into some sort of relationship to the conditions of country life. But in reading through it we are not convinced that the Board has grasped the fundamental difference between the conditions of life, and even the outlook upon life, in the country and in the town. The reader instinctively feels that no new method is being evolved, but the old system (which has not been a conspicuous success in the rural district) is simply making a second appearance in a dress with some agricultural trimmings. The organiser who is responsible for giving rural significance to the schools is at present "primarily an expert in agriculture in the narrower sense, and it will probably always be desirable that this should be the case." But why? Why not men who primarily possess insight and imagination, who can get to the essentials of the problem, and devise methods of dealing with it? However, teachers and country authorities alike realise its importance, and we may be closer than we think to the new rural education.

THE NOTIFICATION OF TUBERCULOSIS.

FOR some time past public opinion has slowly but gradually been educated on the question of the infectivity of pulmonary and certain other forms of tuberculosis. When notification of phthisis as an infective disease was first mooted, a loud outcry was raised, not only by the public, but even by medical men. Certain enlightened communities, however, recognising the importance of such notification, early obtained powers to put into operation a system of voluntary notification. It was argued, and very wisely, that until the medical officer of health and his committee could be put in possession of information concerning centres of infection, little could be done to prevent the dissemination of infective material from these centres. It was maintained, further, that notification, voluntary on the part of the patient and his medical attendant, was preferable to no notification at all, in so far that in the first place some information as to the presence of tuberculous patients would be provided, and, in the second, some experience as to the working of the system would be obtained.

The present chief medical officer of the Local Government Board, even when he was medical officer of health for Brighton, has always been in favour of voluntary notification of tuberculosis, whilst so far back as September, 1908, the present President of the Local Government Board announced during the sittings of the International Congress on Tuberculosis at Washington that he had promoted an order that in workhouses and similar institutions the notification of pulmonary phthisis should be compulsory. Mr. Burns has made the study of tuberculosis peculiarly his own, and the further development of notification and the extension of the compulsory clauses of the Infectious Diseases Notification Act to this disease is but the natural outcome of this systematic study by men keenly interested in the preservation of the public health. Moreover, there is a general feeling that even this is not the last of the measures of preventive legislation to be taken.

It is now recognised that tuberculosis is to be stamped out or cured by no single method or system. The centres of infection are so varied, the phases and types of the disease so numerous, and the condition of the patients so diverse that siege must be laid to tuberculosis in very different fashions, as occasion may require. Only after obtaining a knowledge of the individual cases can those in authority set to work to classify them in such manner that appropriate measures may be taken to meet the requirements of these cases, as they are searched out and examined.

The advanced cases of consumption—patients who are left to linger on, badly fed, wretchedly housed and clothed, weak, distressed, and disheartened—are most dangerous centres of infection, and the only satisfactory way to deal with them is to place them in hospitals where, in comparative comfort, relieved from anxiety as to their shelter and daily bread, segregated as regards infection, but visited by their friends from time to time, they may pass the remaining months or years of their life. Remove these, the most dangerous, cases to hospitals—for they are dangerous so long as they remain amongst their fellows—and they become harmless. For other patients dispensary treatment may be all that is necessary; but as experience is gained many of these will no doubt be sent to sanatoria, partly for initial treatment and rest in order that the cure may begin under the most favourable conditions, and the patient may make a "good start," but also in order that he may be educated in the care of himself, and that he may render himself less dangerous to others with whom he may have to live and work.

During the last fifty years the death-rate from tuberculosis has fallen more than 30 per cent. With proper application of compulsory notification and stern tackling of the problems that it will disclose, at least as great, and probably a still greater, fall of this death-rate may be prophesied at the end of the coming couple of decades.

FOOT-AND-MOUTH DISEASE.

APPOINTMENT OF A COMMITTEE OF INVESTIGATION.

THE recurrence of this disease in England during the present year has been a source of grave concern to all engaged in agricultural and live-stock industries. It is, however, a matter for congratulation to the Board of Agriculture, and its veterinary department in particular, that the disease has been stamped out again with such a comparatively small loss. There have been eighteen outbreaks this year, with 467 animals affected, an approximate average of 26 animals in each outbreak. This is truly remarkable considering that foot-and-mouth disease is probably the most rapidly contagious of all epizootics.

During the four years immediately preceding the present year, there were five outbreaks with 127 animals affected, each outbreak being suppressed in little more than a week, at a total cost of a few thousand pounds. This has only been possible as the result of early diagnosis and the immediate slaughter of all affected and contact animals. The importance of drastic and immediate action can be well realised by noting some of the latest Continental returns. In Germany during August alone there were 37,737 outbreaks of foot-and-mouth disease; in July 12,385 were recorded in Holland, 4,097 in Belgium, and 16,027 in France, where it has been estimated that the loss will amount to more than fifteen millions sterling.

The new Minister for Agriculture has therefore taken a very wise step in appointing a committee, as announced in Parliament last week, "to inquire into the circumstances of the recent outbreaks of foot-and-mouth disease and to consider whether any further measures can be adopted to prevent their recurrence." The committee of twelve is to be presided over by Sir Ailwyn Fellowes, and includes the members of Parliament for South Wilts, St. Patrick's Division of Dublin, Barkston Ash, Carmarthen West, Newmarket, and North Bucks, together with Major E. M. Dunne, Mr. R. Carr, Mr. E. E. Morrison, Mr. E. P. Nunneley, and a member of the Central Chamber of Agriculture. They are to be assisted by the veterinary and administrative officers of the Board.

Of greater importance, however, is the proposal to appoint an expert scientific committee to proceed to India, where the disease is unfortunately very rife, to investigate the special characteristics of the disease, its etiology, the means by which it is contracted and spread, and practicable means of prevention. It is to be hoped that tangible results will be attained, so that we can continue to enjoy the markets of the world for our live-stock, as the result of the freedom of these islands from such animal scourges.

DR. W. SUTHERLAND.

IT is with regret that we have observed the report of the sudden death, on October 4, of Dr. William Sutherland, at his residence, Stawell Street, Melbourne, as recorded in *The Melbourne Age*. Dr. Sutherland was born in Scotland in 1859. At the age of ten he went with his parents to live in Melbourne. He obtained a Government exhibition, and finished his preliminary education at Wesley College. From there he went to the University, where he took his Master of Arts degree, obtaining the highest honours each year in mathematics. The winning of the Gilchrist scholarship in his final year enabled him, under the terms of the exhibition, to go to London University College. He was then only twenty years of age. Three years later he returned to Australia, having obtained a degree in science.

From that time until his death Dr. Sutherland devoted himself entirely to original scientific research. He contributed papers to scientific periodicals in America, England, and on the Continent. His first line of thought led him to inquire into the molecular constitution of matter in its various phases of liquids and solids. Later he devoted attention to the subject of viscosity. His papers, which appeared mainly in *The Philosophical Magazine*, are well known to the scientific world. They are distinguished by great width of reading in the latest phases of the subjects he treated, combined with very bold speculation always brought into ample comparison with experimental knowledge. His greatest success was the discovery, in 1893, of the relation connecting the viscosity of a gas with the temperature; the result of a very ingenious, though not quite demonstrative, theoretical argument, and amply confirmed by all subsequent work. His writings were copious in all problems connected with molecular physics, whether they concerned laws of attraction between molecules, the nature of emulsion in its physiological ramifications, the application of electrons and of electrochemical ideas to the properties of matter, the molecular structure of water, or many other subjects. His generalisations were, indeed, so numerous that it was often a difficult task to try to estimate their value. Although Dr. Sutherland had thus contributed a large number of papers to various scientific journals, he never published anything in book form. He preferred to devote his energies entirely to original work and research. For a period he discharged the duties of professor of physics at the Melbourne University during a temporary absence of the occupant of the chair; but in the main he preferred freedom and control of his time. His relations with the University staff were cordial and intimate. He was an examiner at the University and at the College of Pharmacy, and was also connected with the scientific work of the School of Mines.

J. L.

NOTES.

WE are informed that Dr. Glazebrook, the director of the National Physical Laboratory, who has been seriously ill since the end of September with enteric fever, is now making satisfactory progress. After so long an attack of fever his recovery must necessarily be somewhat slow, and it may yet be some little time before he can be regarded as convalescent; but there is good reason to hope that the recent marked improvement may be maintained.

THE case of the *Hawke* and *Olympic* collision, which is now before the Admiralty Courts, is directing considerable attention to the influence of passing vessels upon each other, particularly when those vessels are travelling in the same direction at speeds not differing greatly from each other. Experiments are now being made at the William Froude Tank of the National Physical Laboratory, with models of the *Hawke* and *Olympic*, to test whether such an influence was present and acting at the time of the collision. The president of the Admiralty Court and the various counsel paid a visit to the experiment tank on Saturday last and witnessed a large number of experiments with the models. These were of wax, and were towed from the carriage, or bridge, which spans the large waterway of the tank. The general theory of the influence of passing ships upon each other is the outcome of the "stream-line" theory of the late Prof. Rankine; and we hope to give a fuller account of this shortly.

AN earthquake of unusual strength was felt on November 16 at about 9.25 p.m. (Greenwich mean time) in the south of Germany, throughout Switzerland, and in

the east of France and the north of Italy. It was followed by two others of less importance early on November 17, one shortly after midnight, the other at about 3 a.m. The reports so far available in this country are singularly meagre. There does not seem to have been any loss of life, but slight damage to property occurred in several places, such as Constance, Stuttgart, Freiburg, Mülhausen, and Hechingen, and, though it is difficult to credit the statement, at Munich. Leaving the last-named place out of account, the area of slight damage is about 140 miles long from east-north-east to west-south-west, and 90 miles wide, and contains about 10,000 square miles. The centre may have been about 10 miles to the north of Schaffhausen. The shock was felt so far as Dresden, 310 miles from this point, so that the disturbed area may have contained as much as 300,000 square miles. It is thus probable that the focus was situated at some depth. The vibrations were recorded at several distant observatories—in this country at Shide and West Bromwich. At Heidelberg, Besançon, and Potsdam the recording levers were deranged or broken.

A DISCOVERY of remarkable prehistoric burials has been made by the Broadstairs Archæological Society in the grounds of a private school. During excavations a series of Saxon graves came to light. Under these, and therefore of an earlier date, were found a number of graves arranged round a circular trench, in which the bodies had been buried with the arms and legs flexed. Nothing was found to give a clue to the date of these circular burials; but Mr. F. G. Parsons, who is making an examination of the bones, is of opinion that they belong to the Bronze age. Whatever the antiquity may prove to be, the find is one of importance, for we know very little of the inhabitants of Kent prior to the Saxon period. The remains, which are somewhat fragmentary, are to be placed in the museum of the Royal College of Surgeons, where they may be compared with other finds of a similar nature which have been made in the south-east of England. In the current number of the Journal of the Royal Anthropological Institute (vol. xli., p. 101) Mr. Parsons gives an interesting description of Saxon remains found in a cemetery near Folkestone.

FURTHER details of the Wright gliding experiments are now to hand. On Tuesday, October 24, the best flights were made in the teeth of a wind which was recorded by a gauge raised 12 feet from the ground to be blowing at 50 miles an hour. Orville Wright made nineteen successive glides, one, the last, enduring for 9m. 45s., and extending over a distance of nearly a quarter of a mile. During his seventeenth glide he remained stationary in the air for 5m. 11s., the whole glide lasting 7m. 15s. The following day twenty glides were made by Orville Wright and Alexander Ogilvie, but as the wind was slight nothing remarkable was achieved. On October 26 twenty-four flights were made, one of which lasted 2m. 15s. This was the last day before breaking up the camp. The new automatic stability device, which had arrived, was not fitted to the machine, and its trials were postponed to a later date. To the description of the machine used, given in NATURE of November 9, the following details may be added:—As the cutting-down of the skids necessitated the removal of the "blinkers," a vertical surface or keel-plane was fitted to the front edge of the main planes immediately to the right of the pilot, the object being to keep the glider directly head on to the wind. Furthermore, a boom projecting in front of the main planes some five feet carried a bag of sand, as the pilot's weight was insufficient to keep the machine level in high winds.

PROF. W. H. PERKIN, F.R.S., and Prof. E. Rutherford, F.R.S., have been elected corresponding members of the Munich Academy of Sciences.

THE Institute of Chemistry announces that Mr. Bertram Blount will deliver the second lecture on "Cement" at King's College, Strand, W.C., on Friday, December 1.

PROF. ANDREW MCWILLIAM, professor of metallurgy in the University of Sheffield, has been appointed by the Government of India to the newly created post of metallurgical and analytical inspector of steel in India.

WE learn from the *Revue scientifique* that the German Society of Aërial Navigation has constructed at Feldberg, in the Schiefergebirge, a geographical observing station for the study of aërial currents, and for the issue of a service of wind warnings.

THE council of the Royal Meteorological Society has awarded the Symons gold medal to Prof. Cleveland Abbe, of the United States Weather Bureau, in recognition of the valuable work which he has done in connection with meteorological science. The medal will be presented at the annual meeting of the society on January 17, 1912.

WE learn from *Science* that Mr. Waldemar Lindgren, who has been connected with the U.S. Geological Survey since 1884, and since 1907 has been in charge of the investigations of metalliferous deposits and of metal statistics, has been elected chief geologist, in succession to Dr. C. Willard Hayes.

THE Société Française de Physique has arranged a series of nine lectures on "Modern Ideas on the Constitution of Matter," by Madame Curie, Profs. Langevin, Perrin, Weiss, and other distinguished physicists. They are to be delivered on Saturday evenings during the next four months either at the Sorbonne or at the rooms of the society, and are open to all members of the society. The example set by the French society might with advantage be followed by some of our societies.

AT a meeting of the executive committee of the British Science Guild, held on November 15, it was announced that arrangements were being made to hold occasional evening meetings of the members, at which papers or lectures would be read, to be followed by discussions. Also further papers have been received on the subject of the conservation of the natural sources of energy, and it is hoped to publish this report before the close of the year. The subjects of coordination of charitable effort and postal reform were also discussed.

ON previous occasions we have referred to the mining operations made this year by the Duke of Sutherland to determine if the gold deposits in the Kildonan district of Sutherland could be worked at a profit. In our issue of September 28 (vol. lxxxvii., p. 425) we announced that information received from the field showed the experiments had been a financial failure. The report of Mr. William Heath, the expert entrusted with the operations, has now been commented upon in the Press. Mr. Heath says:—"This field cannot be worked by any method so as to realise on the most liberal estimate anything like half the working expenses."

THE president of the Royal College of Surgeons, Sir H. Butlin, delivered at the college two lectures (November 13 and 15) on "The Parasite of Cancer." Sir H. Butlin maintains that the cancer cell is a new creation, an independent organism most closely resembling a protozoon,

which lives as a parasite in the body of the animal which is suffering from cancer. He apparently does not suggest that it is a parasite derived from without, but that the host by some inscrutable means has fashioned it out of its own tissues.

THE death is announced, in *The Times*, of Dr. W. W. Webb, at Exeter, in his fifty-fourth year. Dr. Webb resided for some years at Netley, and was appointed curator of the Natural History Museum at the Royal Victoria Hospital, being awarded the Martin memorial gold medal and the Sir Joseph Fayrer's prize for pathology at Netley in 1883. He was the author of a guide for intending candidates for commissions and for junior officers of the Indian Medical Service, a manual of vaccination, and a work on the currencies of the Hindu States of Rajputana.

MR. JOSEPH COLLINSON, writing from the Animal Friend Society, asks for protection for the badger, as this sadly persecuted animal has dwindled down almost to extinction. Many well-known landowners have made praiseworthy efforts to protect the badger, and warmly advocate his preservation. "The protection of the badger," remarks Sir Harry Johnston, "ought to be made universal in the law of the land, quite as much as in the case of interesting wild birds," a sentiment which will receive the approbation of all who are interested in preserving the wild fauna of their native country. No other animal has made such a wonderful struggle for existence; and it is hoped by Mr. Collinson that protests may be made in time to prevent his total extermination.

THE second International Congress of Entomology will be held at Oxford on August 5–10, 1912, under the presidency of Prof. E. B. Poulton, F.R.S. Further particulars will be announced shortly. The executive committee proposes to find for members of the congress lodgings in the town, or rooms in one or more of the colleges at a moderate charge; rooms in college will be available only for men. The executive committee invites an early provisional notice of intention to join the congress, in order to be able to make the arrangements for the necessary accommodation. The proceedings of the first congress are in the press and will be published shortly. All communications and inquiries should be addressed to the General Secretary of the Executive Committee, Dr. Malcolm Burr, c/o the Entomological Society of London, 11 Chandos Street, Cavendish Square, London, W.

IT was suggested at a meeting of the Anglo-German Friendship Society, held at the Mansion House on November 2, under the presidency of the late Lord Mayor, that an Anglo-German Exhibition should be held in London in 1913. We learn from *The Times* that the idea has been favourably received, and an influential committee has been formed to forward it, under the presidency of the present Lord Mayor, consisting of the Lord Chancellor, the Duke of Argyll, Lord Brassey, Lord Avebury, Lord Weardale, Lord Courtney of Penwith, Lord Shuttleworth, Sir Frank Lascelles, Sir West Ridgeway, Sir Vezey Strong, Sir William Mather, Sir Ernest Tritton, Mr. Harry Lawson, M.P., and Mr. Alfred de Rothschild, with Mr. Cyril Rhodes, the honorary secretary of the Anglo-German Friendship Society, as honorary secretary.

THE London meeting of the Institute of Metals will be opened at the Institution of Mechanical Engineers on Tuesday, January 16, when the president-designate, Prof. W. Gowland, F.R.S., will deliver his inaugural address on the subject of "Copper and its Alloys in Early Times." The whole of Wednesday, January 17, will, if necessary, be devoted to the reading and discussion of a number of papers, amongst which may be mentioned the following:—Properties of certain copper alloys at high temperatures, G. D. Bengough; further experiments on the inversion at 470° C. in copper-zinc alloys, Prof. H. C. H. Carpenter; the influence of oxygen on copper containing arsenic or antimony, R. H. Greaves; the nomenclature of alloys, Dr. W. Rosenhain; poisoned brass, and its behaviour when heated in vacuo, Prof. T. Turner; and a paper by Dr. Carl Benedicks, of the University of Stockholm, dealing with some novel experiments on a zinc-antimony alloy.

WE regret to record the death of Mr. Eugene William Oates, at Edgbaston, on November 16, at sixty-six years of age. Like many other Indian officials, Mr. Oates, who served (chiefly, we believe, in Burma) for thirty-two years in the Public Works Department of India, devoted his leisure time to the study of the ornithology of the country in which he was long resident. His earliest ornithological work appears to be a "List of the Birds of Pegu," published in Calcutta in 1881, and a couple of years later appeared his "Handbook to the Birds of British Burmah, &c.," published in London, in two volumes. This was followed, in 1898–9, by a "Manual of the Game Birds of India," which likewise formed two volumes, and was published at Bombay. Somewhere about this time he appears to have retired from the service of the Indian Government, for in 1889–90 his name appears as editor of the second edition of Mr. A. O. Hume's "Nests and Eggs of Indian Birds," published, in three volumes, in London. His knowledge of Indian ornithology led Dr. Blanford to select Mr. Oates to write the first two volumes on birds in the "Fauna of British India," which appeared respectively in 1889 and 1890; and later he was engaged by the trustees to compile the "Catalogue of Birds' Eggs in the British Museum," the first volume of which was issued in 1888 under his own name, while in the other three this appears in conjunction with that of Captain Savile Reid. Mr. Oates's knowledge of Indo-Burmese ornithology was very extensive, and his work careful and elaborate.

THE committee of the British Antarctic Expedition has made an earnest public appeal for further contributions towards the support of Captain Scott's expedition in Antarctica. Through ill-fortune, unforeseen expenses have been incurred. On her voyage south after leaving New Zealand on November 29, 1910, the *Terra Nova* experienced terrible weather, and the damage done to the ship has entailed a heavy bill for repairs; and the cost of new stores to replace those lost on this voyage has to be met. After defraying these unexpected disbursements the money left will be hardly enough to enable the committee to pay until the end of March, 1912, the allowances of the wives and relatives of the officers and men of Captain Scott's party. On these accounts alone the committee must somehow raise more money. In addition, however, it is imperative that there should be no delay in securing further funds if the honour of first reaching the South Pole is to be secured for Captain Scott. The *Terra Nova* on her journeys unexpectedly came across the Norwegian expedition under Captain Amundsen, who also is trying to reach the Pole. The committee asks for 15,000*l*. by December 1, so that a telegram may be sent before the *Terra Nova* sails south to reassure Captain Scott that the necessary funds will be forthcoming. We agree with the committee that it would be pitiful if Captain Scott and his party were allowed to fail for want of financial support. We are confident that the appeal to the patriotism of our men of

wealth will not be in vain, and that the honour of this country in the world of science and exploration will be maintained by the generosity of the wealthy men at home and the efforts of the men of action now in south polar regions. Contributions should be sent to the treasurer, Sir Edgar Speyer, at 7 Lothbury, London, E.C.

THE advantage of the application of physiological knowledge to the problems of Egyptian archæology is shown in a clever explanation of the origin of the representation of an ancient standard found on the slate palette of King Narmer, which was discovered at Hierakonpolis, in Upper Egypt. It appears again in a specimen of the twelfth dynasty unearthed by Prof. Flinders Petrie below the palace of Apries, at Memphis. Dr. C. G. Seligmann and Miss M. A. Murray, in the November number of *Man*, point out that this curious figure represents the placenta, which is still, according to Mr. J. Roscoe, held in reverence by the Baganda, as it is supposed to contain the external soul of the chief, and is hence preserved at his birth. It was carried in procession by a special official, because the safety of the reigning sovereign was believed to depend upon its being carefully preserved.

IN the first part of the Journal of the Royal Anthropological Institute for the current year, Prof. A. Keith examines a collection of skulls, principally those of Negroes from the Congo Free State and Nigeria. These constitute four groups: those from Nigeria, the Congo, the Korawp, on the frontier of the German Cameroons, and a group of tribes including the Ekoi and Kabila of Nigeria, and the Fortit and Bongo of the Nile region. From the present distribution of the Negro tribes in equatorial Africa, Prof. Keith comes to the following conclusions:—There has been free intermigration; in the course of their evolution, the tendency of one tribe has been towards the accentuation of one set of characters, of another towards another set. Thus the Dinka acquire high stature and narrow heads; the typical Nigerians low stature and narrow heads; the Basoko wide, short heads and low stature; the Buruns wide heads and high stature. Interbreeding may have played its part; but if it had played a great part we should have found greater physical uniformity than there is. The influence of Arab blood on these tribes has probably been exaggerated.

THE Bulletin of the Johns Hopkins Hospital for September (xxii., No. 247) contains articles on Zabdiel Boylston, inoculator, and the epidemic of smallpox in Boston in 1721, by Dr. Fitz; medical notes on the "Divine Comedy" of Dante Alighieri, by Dr. Dernehl; and on "Molière and the Physician," by Dr. Kahn. A new department has been created in the Johns Hopkins University, to be known under the general title "Art as Applied to Medicine." Its purpose is to bridge over the gap existing between art and medicine, and to train a new generation of artists to illustrate medical journals and books. The instruction given is designed for the needs of two classes: (1) for medical students, and (2) for artists. The department is in charge of Prof. Max Brödel, and a synopsis of the two courses is given.

A REPORT by Dr. F. J. H. Coutts, on an inquiry as to condensed milks, has been issued by the Local Government Board. It contains much important matter on the history, methods of manufacture, composition, and use of condensed milk, with suggestions as to administrative control, labelling, &c. Condensed milk occurs as full-cream or machine-skimmed, and may be sweetened, partially sweetened, or unsweetened. The composition of the different brands varies somewhat; *e.g.* in the full-cream and fully sweetened the fat varies from about 9·0 to 13·7 per cent., and the sucrose (generally beet sugar) from 37·2 to 41·5 per cent. The condensed milks, except occasionally in the unsweetened brands, which are sterilised, generally contain some micro-organisms (up to several thousand per cubic centimetre), but they show no disposition to multiply either in the unopened or in the opened tins, as a rule. Diluted condensed milk, however, becomes a favourable medium for the growth of bacteria. The process of condensation appears to be fatal to the tubercle bacillus. The importance of condensed milks is in connection with infant feeding. The skimmed condensed milks are to be absolutely condemned for this purpose, owing to the small fat content. Infants fed on condensed milks seem to suffer from more infantile ailments, and the mortality is higher among them, than among those fed on cow's milk. As regards cost, the condensed milks are slightly more expensive than equivalent amounts of cow's milk and sugar. The labelling of some of the brands is very misleading to the poorer and illiterate mothers who principally use them. It is suggested that the skimmed brands should be labelled as unfit for infant feeding, and that some declaration of the content of fat and of substances foreign to milk should be obligatory on the labels.

A SIGNED portrait, accompanied by a memoir, of the late Mr. G. H. Verrall, the distinguished authority on British flies, forms the chief feature in the November number of *The Entomologist's Monthly Magazine*.

IN referring to his bird-marking experiments in the November number of *British Birds*, Mr. Witherby remarks that "the number of birds marked has steadily increased until this year the splendid total of just 9500 has been reached. In the first year of the inquiry only 2200 rings were used, but in the next year 7900 were placed, so that the number of birds 'ringed' by the readers of *British Birds* now amounts to nearly twenty thousand." The large increase in the number of rings implies, of course, increased expenditure, to meet which additional contributions are solicited.

IN its report for the year ending June 15, 1911, the Northumberland Sea-fisheries Committee gives a summary of the results of the experiments in marking fish and crustaceans which have been carried on locally during the last few years, together with tables and charts. The experiments in breeding lobsters show that an abundant supply of absolutely pure sea-water is essential to success; and it is interesting to note that during the year one of the officials had the opportunity of observing a lobster during the process of shell-changing. Experiments on Holy Island show that a vast area is available for the culture of mussels, to be used either as bait or food; and observations are also recorded on the spawning of cod.

To *Naturwissenschaftliche Wochenschrift* for October 29 Dr. A. Kobelt contributes a long article on the physiological origin of markings and colour in the animal kingdom. Attention is directed to the prevalence of pigment in the neighbourhood of the great sensory and nervous structures, as exemplified by the dorsal stripe of many mammals and some lizards, the dark lateral line of fishes, the frequency of dark markings on the muzzle, and especially the concentration of colour in the eye and its neighbourhood. The hue of the ground-colour of animals is attributed by the author to the existence of an equilibrium between the effects of light-stimulus and the influence of the sense-organs, which leads to an equality in, and a large

increase of, the sensory cells. Disturbance of this equality gives rise to colour-markings. Apparently Dr. Kobelt does not believe in protective coloration.

THE Purdue University Experiment Station has taken a leaf out of the business man's book, and freely advertises its results among farmers. The Bulletins, a number of which are to hand, are written in a manner likely to attract, and demonstrate that the yield of maize can be considerably increased on the ordinary farm without a great expenditure, but solely by the adoption of improved varieties or better fertilisers. New crops have been introduced, and improved and more economical rations have been drawn up for dairy stock.

WE have received from the United States Department of Agriculture, Bureau of Entomology, catalogue by E. R. Sasscer of recently discovered Coccidæ and by D. Moulton of the North American Thysanoptera, and also an annotated bibliography of the Mexican cotton-boll weevil by F. C. Bishopp. Publications of this type are extremely valuable in enabling investigators to find their way through the appalling number of entomological publications that are put out at a rate probably unequalled in any other subject.

The National Geographic Magazine for September is largely devoted to two studies of Troglodytes, one by Mr. F. E. Johnson describing those of southern Tunisia, the second by Miss E. H. Brewer the cave-dwellers in Cappadocia. Some French officers divide the Tunisian Troglodytes, whose presence in that region is noted by the historian Sallust into three groups: those living in excavations in the ground, those occupying caves or holes in the hillside, and those living in houses superimposed one upon the other, the higher chambers being reached by precarious staircases or stones projecting from the walls. The Troglodytes in the Uskub Valley in Asia Minor occupy holes excavated in curious rock cones. Prof. Sterrett, of Cornell University, who has studied them, believes that this form of dwelling dates so far back as the Hittite period. Both these accounts of two remarkable races are illustrated by a series of admirable photographs.

IN the *Zeitschrift der Gesellschaft für Erdkunde* (No. 7) Dr. A. Rühl discusses the part played by isostasy in the formation of peneplains. He considers that when an elevated land mass is subjected to long-continued erosion the isostatic equilibrium is destroyed, and as a result, after a greater or less period of time, a new upward movement will take place, but to a less extent than originally. Local conditions will determine at what stage these isostatic movements will occur. The development of the earth's surface would not be a continuous operation, but rather one strongly periodic in character in which short periods of active orogenetic and epeirogenetic movement would be succeeded by relatively long periods of erosion. Orogenetic movements occurring would cause fracturing of the earth's crust, and eroding agencies would become active, removing material and redepositing elsewhere. This will destroy the isostasy, and sooner or later a warping or tilting of the whole land mass will occur.

PART iii., vol. xli., of the Records of the Geological Survey of India contains the usual annual statistics of the mineral production of India, the year here dealt with being 1910. Upon the whole, the production is just about stationary, the value of the output showing an increase only of some 12,000*l.*, whilst its total is 7,700,000*l.* The principal item, as before, is coal; the total output is just over 12 millions of tons, showing an increase of about 177,000 tons over 1909: on the other hand, prices have fallen again to about what they were before the boom of 1907–8, and may be looked upon as at about a normal level. The industry is evidently in a sound condition: the output per miner shows a satisfactory increase, and exports have gone up and imports have gone down by 43 and 36 per cent. respectively. Owing to the above-noted fall in price, the value of the coal output in 1910 is 324,321*l.* lower than in 1909; but, as explained, this is a healthy symptom so far as the coal industry is concerned. The next most valuable output on the list is that of gold, which is practically stationary at 2,200,000*l.* These two minerals are by far the most important amongst Indian mineral products, accounting for about three-fifths of the total value. The production of manganese ore shows a fair increase, the total for 1910 being just over 800,000 tons; prices were also rather better than they were in the previous year, so much so that whilst the quantity produced was increased by 20 per cent., its value was increased by no less than 40 per cent. The production of both mica and petroleum has fallen off during the year under review. Upon the whole, it may be said that whilst not chronicling any brilliant results, the statistics before us show a steady progress in the mining industry of our Indian Empire.

THE excessive rains of Saturday and Sunday last have occasioned considerable and extensive floods at many places in the south and east of England, and in Kent and Sussex a great deal of land is under water. The Weather Report issued by the Meteorological Office for the week ending November 18 shows that the total rainfall for the period was largely in excess of the average over the entire kingdom. The heaviest falls occurred in Scotland and Ireland, where in parts the rainfall for the week was about three times the average amount. Falls of more than an inch in twenty-four hours occurred in all parts of the kingdom; and at Worthing the measurement for the three days ending November 18 was 3·27 inches. The autumn rainfall for the eleven weeks commencing with September is now in excess of the average in all districts except in the north and west of Scotland, the north-east of England, and the Midland counties. The greatest excess for the autumn is 3·00 inches in the Channel Islands, which is followed by 2·85 inches in the south of Ireland and 2·73 inches in the south-east of England. The greatest deficiency of rain since the commencement of the year is 6·56 inches in the Midland counties, where the aggregate fall, so far, is only 16·53 inches. The temperature last week was largely in excess of the average in all the English districts, the excess amounting to nearly 5° in the east of England. The duration of bright sunshine was generally deficient.

THE meteorological chart of the North Atlantic for November issued by the Deutsche Seewarte gives an interesting account of a hurricane experienced on July 12 in the South Atlantic, near lat. 30° and long. 30°, by four out of five sailing vessels which left Chilian ports between May 17 and June 14, the tracks of which are laid down for the whole voyage to the English Channel. It is noteworthy that the storm occurred with a relatively high barometer; the synoptic charts drawn for July 10–13 show that a shallow depression lay over the coast of central Brazil on July 10, and that on the following day it had divided into two parts, the centre of one being on the coast in 20° S. and the other in about 26° S., long. 39° W. From the chart of July 12 it appears that the two systems had coalesced, and had travelled in a south-easterly direction. The atmospheric conditions are considered to be very striking (notwithstanding that it was the southern winter),

the more so as the disturbance proceeded from the somewhat low latitude of 20° S.

THE marine turbine speed-reducing gear fitted by the Westinghouse Company, of Pittsburg, to the United States collier *Neptune* is described in *The Engineer* for November 17. This is a modified form of the Melville-Macalpine gear with double-helical pinion and spur wheel. The power transmitted is 4000; the pinion keyed to the turbine shaft runs at 1250 revolutions per minute, and the screw shaft at 130—a reduction of nearly 10 to 1. The pinion shaft is not carried in rigid bearings, but is borne in a long sleeve, which is provided with three hydraulic pistons above and three below. The movement from the central position is trifling—two or three thousandths of an inch—but the liquid correction gives the gear a certain amount of elasticity, reduces shock and noise, and conduces to the sweet running of the gear. The *Neptune* has given great satisfaction on its trials.

WITH the view of ascertaining the resistance of reinforced concrete strong-rooms to attack by oxy-acetylene blow-pipes, tests were recently made on a slab prepared by the Indented Bar and Concrete Engineering Company, of Westminster. The results are described in *The Engineer* for November 17. The oxy-acetylene blow-pipe was applied to the slab for twenty-four minutes, at the end of which period, after much raking out of the resulting glass formed by the fusion of the sand, and accompanied by a deafening roar from the blow-pipe, a hole 3·5 inches in diameter was made through the slab. Whenever a steel bar was met the metal-cutter, *i.e.* a stream of pure oxygen directed on to the white-hot steel, was brought into action, and the steel instantly fused away. The concrete was the material which gave the trouble, the metal-cutter being powerless to act upon it. The same thickness of steel of any grade could not have resisted the metal-cutter longer than about four minutes. The test slab was 6 inches thick; 0·55 cubic foot of oxygen and 0·45 cubic foot of acetylene were consumed in the test, which clearly is strongly in favour of reinforced concrete as contrasted with steel.

A COPY of the Year Book for 1911 of the Indian Guild of Science and Technology has been received. The object of the guild is to cooperate in promoting the knowledge and application of pure and technological science in India with a view to the improvement of the methods of economic production and the amelioration of the sanitary condition of the people. Prof. Smithells, F.R.S., is the general president of the guild; and among the list of patrons we notice the names of Sir Henry Roscoe, F.R.S., Sir William Ramsay, K.C.B., F.R.S., and Prof. O. N. Witt. The year book runs to 135 pages, and contains an official report of the annual general meeting, held on December 19, 1910, of the activities of the various sections, and the speeches at the annual dinner. In addition, a number of scientific articles, many of them concerned with pressing Indian problems, are included. Altogether the guild, which is only in the third year of its existence, has entered upon a career of great usefulness.

MESSRS. NEWTON AND CO., 3 Fleet Street, E.C., have just issued a supplementary list of lantern-slides, in which several sets of slides of scientific interest are included. Among these subjects are remarkable examples of achievements of photography, pictures taken by Prof. R. W. Wood with ultra-violet and infra-red rays, photographs of snow crystals taken by Mr. W. A. Bentley, wild flowers, glaciers, and other scenes in Switzerland, and architectural hygiene.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF BROOKS'S COMET, 1911*c*.—With the three-prism slit spectrograph (No. iii.) and a small objective-prism spectrograph of 10 cm. focal length, both attached to the Pulkowa 30-inch refractor, Prof. Belopolsky secured several photographs of the spectrum of Brooks's comet during October. Eight hours' exposure with the slit spectrograph on October 4, 5, and 6 showed the bands 473 $\mu\mu$ and 431 $\mu\mu$ clearly, and others faintly; in each case the several maxima in each band were measured, and the wave-lengths are given to six figures. Measures of the radial velocity of the comet gave +15 km., agreeing with the ephemeris.

With the smaller spectroscope monochromatic images of the comet were found at 560, 516, 473, 405, and 388 $\mu\mu$, each image being sharply defined on the red side; special measures gave the values 388·36 $\mu\mu$ and 387·52 $\mu\mu$. Bands in the continuous spectrum extended from 420 to 421 $\mu\mu$ and from 402 to 405 $\mu\mu$. On October 1 the bands were equal in intensity, but on October 10 that at λ 388 was the brightest; this band only gave a faint trace of the tail (*Astronomische Nachrichten*, No. 4535).

THE CHEMICAL UNITY OF THE COSMOS.—In the current number of *Scientia* Prof. Fowler has an interesting article in which he sums up the evidence showing the chemical unity which exists among all the bodies of the visible universe, so far as our present means permit us to examine them. Kant and Laplace suggested such a unity; but it was not until Kirchhoff and Bunsen, in 1859, supplied the key which opened up to us celestial spectrum analysis that the suggestion could be practically tested. Several factors still interfere in many cases with the proof of absolute coincidence of wave-length in comparing radiations in different spectra, but Prof. Fowler believes that all celestial spectra will sooner or later come within the scope of laboratory reproduction. Most of the strong lines in the solar spectrum are already origined, and the sun has been shown to take its place in an orderly sequence of stellar forms. Then, again, the study of the various elements, under varying laboratory conditions, initiated by Sir Norman Lockyer, has provided us, so far as the main variations in celestial spectra are concerned, with terrestrial parallels for the stellar departures from the sun's spectral features.

SUN-SPOTS AND FLOCCULI IN 1910.—In addition to the values for December, 1910, No. 12, vol. i., of the *Boletin Mensuel del Observatorio del Ebro* contains the *résumé* of the solar and meteorological observations made during 1910. The spot areas were low throughout the year, and no spots were recorded at all in August, September, and December. The reduced area for spots, in both hemispheres for the whole year, was 165 millionths of the solar hemisphere, and for flocculi the analogous value was 401 hundred-thousandths, the ratio between the two being 24·3. Taking the hemispheres separately, the values for the northern was 42, and for the southern 123, millionths for spots, and 114 and 287 hundred-thousandths for flocculi. The mean heliographic latitude of spots was 10·1, and for flocculi 10·2. During the year there were 301 groups of flocculi occurring with spots and 525 occurring without, and the tabulated summary shows that those groups occurring with spots were decidedly of a more compact character than those occurring without.

ASTROGRAPHIC CATALOGUE, PERTH (W.A.) SECTION.—In the preparation of the International Astrographic Catalogue the section dec. −31° to −41° was allotted to the Perth Observatory, West Australia, which has just published the first volume of results. The complete measures will occupy thirty-six volumes; and the present issue, the first to be completed, is vol. iv. The method of work is briefly explained by Mr. Cooke, but a general introduction will appear later. It is believed that the faintest stars shown on the centre of the Perth plates are of about mag. 11·5, those at the extreme corners 10·5; and the present volume contains the measures of the rectangular coordinates and magnitudes of 13,636 star images between R.A. 18h. to 24h. on plates with centres in declination −32°.

THE CASE-HARDENING OF STEEL.

THE autumn meeting of the Iron and Steel Institute was to have taken place in Turin, but unfortunate circumstances rendered this impossible. None the less, a series of important papers by Italian authors were presented—and taken as read—at the meeting held recently in London. Most of these papers were of the nature often met with at foreign meetings of this institute—*i.e.* records of metallurgical resources and achievements of the country. On this occasion, however, two Italian papers of a different character were laid before the institute. These deal with the case-hardening of steel, and are both from the pen of the well-known Turin metallographer Prof. F. Giollitti, whose name proclaims his close relationship to the present Prime Minister of Italy.

The two papers in question are entitled "On Case-hardening by Means of Compressed Gases" and on a "New Industrial Process for the Case-hardening of Steel." The striking fact brought out by these papers is that the Italian metallographers who have worked on this subject have evolved order out of chaos by treating the whole question as one of physico-chemical equilibrium between the various solids and gases present during the process. It is to be regretted that Prof. Giollitti did not carry out his avowed original intention of giving a detailed summary of the more important researches on this subject conducted by him and his collaborators at Turin, but the mere bibliography of some fifteen memoirs is sufficiently impressive. The results of these researches are, however, summed up by the author in his present paper in a series of conclusions which are very definitely laid down. If we may accept Prof. Giollitti's statement that his views are fully established, the fundamental facts of case-hardening are as follows:—

(1) Solid carburising agents, without the intervention of gases, have only a slight action.

(2) The specific effect of nitrogen is very weak, and only in the presence of cyanides, ferrocyanides, &c., does the effect of volatile nitrogen compounds become marked.

(3) The specific carburising effect of carbon monoxide is enormously greater than that of any solid cementing agent. Pure carbon monoxide carburises iron at all temperatures between 700° C. and 1300° C., and it produces a greater depth of carburisation in a given time than any other carburising agent. Both the depth and intensity of the cementation can be accurately regulated, as they are governed by equilibrium conditions, which can be definitely ascertained and adhered to.

(4) The use of carbon monoxide as the principal cementing agent makes it possible to obtain softer and better graded cementation than is obtainable by other means.

The new industrial process which Prof. Giollitti bases on his experimental results is, in effect, a specially mechanically arranged furnace, which makes it possible to charge and discharge a vertical muffle with the articles to be case-hardened in a very short time. So soon as the muffle is charged with the steel, which is introduced at a red heat, the remaining free space of the muffle is filled with hot granulated carbon, which, the author tells us, flows into the interstices like a liquid. Then a current of carbon monoxide or of dioxide is passed in at a measured rate for a definite time and at a measured temperature, and any desired degree of hardening can be obtained. The effect of the direct contact of the steel with the solid granular carbon appears to be the production of a thin outer skin of very highly carburised steel, while the effect of the gases gives a less highly carburised region extending for some depth into the metal. In the Giollitti muffle it is possible to withdraw the solid granulated carbon at any desired stage, and to continue the cementation with the gas alone, merely leaving enough carbon in the muffle to secure equilibrium of the gases (CO and CO_2) with solid carbon. Tables of analyses are given which show that the result of such treatment is somewhat to lower the carbon concentration of the extreme outside layer and to reduce the carbon concentration gradient inwards to almost any desired extent. This treatment, therefore, removes the risk of cracking and shelling which arises from the rapid changes in carbon content which occur in articles case-hardened in the ordinary way, and more especially by the use of cyanides or ferrocyanides. By the new method it is claimed that cementation of very great depth can be safely obtained, even with special alloy steels, which tend to become "rotten" on the surface when cased by other means. Whether the Giollitti muffle and method will realise all these expectations practical experience alone can show, but there is no doubt that these Italian investigators have thrown a flood of new light into a formerly obscure region of steel metallurgy.

The character of this new light is perhaps more clearly shown, so far as the scientific point of view is concerned, in the paper by Giollitti and Carenvali on case-hardening in compressed gases. The work described in this paper is based on the researches of Schenk on the equilibrium of the systems consisting of Fe, C, CO, and CO_2; Fe, Fe_3C, CO, CO_2; Fe, FeO, CO, CO_2, and other systems consisting of the mutual compounds of the elements iron, carbon, and oxygen at various temperatures and pressures. The experiments of the present authors were conducted by means of a small electric resistance furnace placed inside a steel cylinder, and partially filled with both granular carbon and steel specimens, into which compressed carbon dioxide was fed at known rates. The authors found, in general, that the rate of cementation increased with the pressure employed, but they also found that when certain pressures were exceeded, in spite of their intimate contact with incandescent solid carbon, the surfaces of the steel specimens became thickly coated with oxide, although vigorous cementation had taken place in the metal immediately beneath the oxide layer. Thus they show the photomicrographs which are reproduced in Figs. 1 and 2; in No. 1 we see the section of a carbon steel close to the surface, which was covered with a thick layer of oxide, and the highly carburised nature of the steel close to this surface is at once evident. In No. 2 we see the section of an alloy steel (in this case a nickel-chrome steel) which exhibits an altered, highly carburised layer close to a deeply oxidised surface; the magnification in both cases is 65 diameters.

FIG. 1.

FIG. 2.

In the case of chrome-steels such a paradoxical result had already been observed by Charpy, who expressed his results by stating that apparently in the action of carbon-monoxide on iron-chromium alloys the two metals behaved independently, the iron becoming carburised, while the chromium is oxidised. The present authors show that such an opinion is not justified; the explanation of the apparent paradox lies in the equilibrium conditions of the systems referred to above. For every temperature and concentration there is a critical pressure above which oxide, as well as carbide, of iron is present in equilibrium with CO, CO_2, and C. The addition to iron of a baser metal, such as chromium or manganese, lowers this critical pressure

until—in certain alloys—it falls below the ordinary atmospheric pressure, and oxidation as well as cementation takes place. On the other hand, the addition of a "nobler" metal, such as nickel, raises the critical pressure and allows of the use of gases under higher pressures for cementation without risk of spoiling the articles by surface oxidation. Two interesting conclusions are drawn by the authors. The first is that for a given steel there is a limiting pressure for cementation, by means of carbon-carbon-monoxide mixtures, beyond which surface oxidation sets in. The second is that in the case of chromium alloy steels the pressure of CO and CO_2 must be diminished below atmospheric to allow of cementation without oxidation. Since it is only the partial pressure of these gases, however, which comes into effect, this diminution below atmospheric pressure can be produced by simple dilution. It follows, and the authors describe an experimental verification, that in these circumstances oxidation can be avoided by diluting the stream of "cementing" gases (CO and CO_2) with air. The oxygen, of course, combines with the granulated carbon in the furnace to form CO and CO_2 in the proportions required by the equilibrium conditions, while the remaining nitrogen acts as a diluent and produces the desired effect.

We have here a series of remarkable deductions and experimental verifications of facts which appear almost incredible to any steel-worker not conversant with the theory of physico-chemical equilibria; indeed, the practical man will probably find it difficult to believe them until he has tried for himself. None the less, there is here a basis for the rational and scientific conduct and control of a process hitherto largely based on "rule of thumb."

W. ROSENHAIN.

THE INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND.[1]

THE annual volume of the Transactions of the Institution of Engineers and Shipbuilders in Scotland, which at the close of the session 1908–9 had 1650 members upon its roll, contains several valuable papers. The president, Mr. C. P. Hogg, in his address, after passing in rapid review some of the outstanding developments in engineering during the past 100 years, directed attention to some of the problems of the future; in his opinion the nineteenth century demonstrated how to utilise the forces of nature, while the problem of the twentieth century will be how to do so efficiently.

Mr. C. A. Ablett in a paper on electrically driven reversing rolling mills described in detail the Ilgner system, in which the power, supplied under very economical conditions by a steam turbine or a gas engine, is applied to drive a reversing mill. The mill motor is a direct-current shunt-wound machine; interposed between it and the source of power supply is a fly-wheel converter set in order to provide a system by which the mill motor may be started, stopped, reversed, and kept under control in regard to speed without loss of energy, and at the same time to enable a control apparatus of reasonable dimensions to be employed. The electrical equipment of a 36-inch cogging mill at Osnabrück was described as an example of this system, and the paper was illustrated by a series of drawings and photographs of the plant; especial attention was given to the flexible coupling between the fly-wheel and the electrical machines of the converter set.

In the discussion on this paper Mr. T. B. Mackenzie expressed the opinion that German steel makers were able in many cases, owing to their skilful utilisation of waste energy, to roll their steel at lower rates for power than usually obtained in this country; he believed that in the steel works of the future there would be no reciprocating steam engines employed—the whole of the power needed would be generated by gas engines in a central station and distributed electrically to the various mills.

In a paper by Mr. A. Melville, the "Simplex" method of concrete pile foundations was described; the essential principle of this system was the driving into the ground of a 16-inch diameter steel tube closed at the lower end either by a loose point or a pair of hinged jaws, which open when the tube is eventually withdrawn and permit concrete, either plain or reinforced, to be passed through, filling up the entire space originally occupied by the tube simultaneously with the withdrawal of the latter from the ground. This system has now been extensively employed in the United States, and is rapidly coming into use in this country; the cost was stated to be about 2*s.* 6*d.* per cubic foot of pile when no reinforcement was used.

The important problem of the design of surface condensers, more important than ever since the introduction of the exhaust steam turbine, was dealt with in a paper by Mr. R. M. Neilson, who stated that empirical methods must be abandoned, and the area of cooling surface calculated in a rational manner so as to allow a given vacuum to be guaranteed under given conditions. The author proceeded to work out a scheme for the design of condensers, allowing for the varying conditions found in practice, and then offered a series of valuable suggestions as to the most profitable lines on which experimental research might in the future be conducted. In the discussion Prof. Mellanby directed attention to Dr. Stanton's researches into this problem, and Mr. Weir pointed out that in a condenser for a turbine-propelled torpedo-boat he was able with a vacuum of 28·7 inches to secure a condensation of 27 lb. per square foot of cooling surface.

Other papers published in this volume are steamship repairs by electric and autogenous welding, by Mr. H. S. Younger, descriptive of processes by which repairs can be carried out either by electric welding or by means of the oxy-acetylene process on damaged material so as to make it serviceable again; some tests on board ship to ascertain the water consumption of engine-room and deck auxiliaries, by Mr. C. F. A. Fyfe; and Prof. Mellanby's description of a new experimental steam engine at the Glasgow and West of Scotland Technical College.

TICKS.[1]

THE rapid advance that has been made in recent years in scientific and medical knowledge with regard to diseases caused by parasitic Protozoa and other microscopic organisms has had the secondary result of directing attention to the insects or other invertebrate animals which are often the agents in the dissemination of the disease-causing parasites. Mosquitoes, tsetses, and other biting flies, fleas, and other ectoparasites are now being collected eagerly and studied earnestly in all parts of the world, less perhaps by professed zoologists than by medical men and others, to whom the practical importance of these pests is a greater stimulus to investigation than the purely scientific interest which the creatures may possess in themselves. Hence special attention has been directed to the various groups of blood-sucking arthropods so soon as their connection with particular diseases has been made known. Mosquitoes were the first to come into prominence when their connection with malaria was discovered; then biting flies, and especially tsetse-flies, when their *rôle* in disseminating trypanosomiases of animals and human beings was made known; and next fleas have been the subject of close study, when their relation to the spread of plague became apparent. There remain three important groups of ectoparasites: ticks, lice, and bugs. It is well known that ticks play a considerable part in spreading diseases. In human beings, African relapsing fever is caused by a spirochæte transmitted by a tick; hence its popular name of "tick-fever." In animals, various deadly diseases, known collectively as "piroplasmoses," because caused by a minute blood-parasite belonging to the genus Piroplasma, or allied genera, are known to be transmitted by various species of ticks; such are the "red-water" or "Texas-fever" of cattle, and similar diseases of horses,

[1] "Ticks, a Monograph of the Ixodoidea." By G. H. F. Nuttall, C. Warburton, W. F. Cooper, and L. E. Robinson. Part i., Bibliography of the Ixodoidea, by G. H. F. Nuttall, L. E. Robinson, and W. F. Cooper. Price 6*s.* net. Part ii., by G. H. F. Nuttall and C. Warburton. Price 12*s.* net. (Cambridge University Press, 1911.)

dogs, and other domestic animals in various parts of the world.

For the medical or veterinary practitioner, who cannot be expected to be an expert in every branch of science as well as in his own art, it is of the highest importance that the scientific knowledge of the ectoparasites that are likely to disseminate diseases should be brought together and summarised in such a manner as to be accessible to those whose vocation brings them into contact with these pests. Exhaustive monographs of the various blood-sucking invertebrates are of the greatest practical as well as scientific value. The work under review is the first attempt to deal in this manner with ticks, a somewhat repulsive group of arachnids which has attracted the special attention of but few professed naturalists, and of which the literature, though considerable in bulk, is extremely scattered, and much of it inaccessible. Consequently, experts on this group have been rare, and the identification of a species has often been a matter of extreme difficulty.

The main results of the labours of Prof. Nuttall and his colleagues will be to collect together all references to works dealing with ticks, and to give accurate descriptions, accompanied with illustrations, of every valid species of tick in such a way that it will be possible for anyone in any part of the world to identify a tick, of a species already known, by aid of this monograph. The undertaking is therefore one which, if successfully carried out, will fill a great gap and render an important service.

The first two instalments of the monograph are before us. Part i. contains the bibliography of ticks, which covers 68 quarto pages of references. The bibliography is printed only on one side of the paper, so that those who wish to keep it up to date can cut it up and make a card-catalogue of it. Part ii. contains two sections, the first dealing with the classifications of ticks, the second with the genus Ixodes, Latreille, 1795, of which fifty-one valid species are recognised. Following the descriptions of these species, of which all but two are accompanied by illustrations, are notes on the geographical distribution, on doubtful species, and on the biology of Ixodes, and a synonymic list of condemned and doubtful species, together with a list of the collections in which the types are to be found.

A detailed criticism of this work could only be undertaken by an expert writing for experts. We note, however, that the bibliography seems to contain a great many references to works, ancient and modern, which are little more than literary curiosities, and it would, we think, have been useful to separate the chaff from the wheat by indicating in some way those references which advance the scientific knowledge of the group and are to be taken seriously. For our part, we are sceptical as to the utility, in a work of this kind, of references to the opinions of Aristotle, Pliny, and Moses. The fact that the ancients believed ticks to be without an anal aperture may be an interesting "tit-bit," but it is not of much value, scientific or practical, to those who wish to study ticks at the present day. The illustrations are good and very clear, and the work seems singularly free from misprints. Prof. Nuttall has a curious fancy for using inverted commas, in some cases not for quotations, apparently, but for familiar expressions, such as "rattled like peas" or "put in the way of finding their food"; if these are quotations we do not recognise them, nor are we put in the way of finding their source.

A work of this kind tends, by aiding investigation and discovery, to hasten the advent of the period when it will itself be out of date. It makes it easy for anyone to collect ticks, to identify them, and to discover and describe new species; hence long before it is completed it will probably require supplements. The study of these parasites, interesting not only to the practical man, but also to the naturalist, as remarkable instances of adaptation to a mode of life which is peculiar, if to ourselves unpleasant, will be greatly advanced by the publication of this monograph; and both classes of investigators will owe a debt of gratitude to the labours of Prof. Nuttall and his collaborators for raising the scientific knowledge of ticks to a plane in which rapid progress is rendered possible in the future.

SEISMOLOGY AT THE BRITISH ASSOCIATION.

WE have before us the sixteenth report of the Seismological Committee of the British Association. There may be reasons why this particular report should be known as No. 16, but for those interested in seismological literature such a title may be misleading. As a matter of fact, this association has published fifty-two annual reports about earthquakes, some of which, like those by the late Robert Mallet, are reference works for all who are students of seismology. I direct attention to this matter as an indication that Great Britain has not been behind in investigations relating to earth physics. In certain directions it is far in advance of many others.

The first fact to be gathered from this report is that the British Association, in its endeavour to make a seismic survey of the world, enjoy the cooperation of about sixty stations, which are fairly evenly distributed over the surface of our earth. It is remarkable to note that colonial Governments, and particularly cable companies, have established observing stations on many oceanic islands, as, for example, at Cape Verde, Ascension, St. Helena, Fernando Noronha, Mauritius, Seychelles, Cocos, Fiji, and other places. On March 28 this year the Legislative Council of Bermuda passed a "Seismographic Act" enabling the Board of Public Works to purchase and maintain instruments for recording earthquakes. Other colonial Governments have taken similar steps; whilst the English Government gives direct assistance to an International Association which has its headquarters at Strassburg. An item of considerable interest in the report refers to Double and Multiple Earthquakes, about which we read the following:—

"Attention has frequently been drawn to the fact that an earthquake as it radiates may cause a collapse of strata which is in an unstable condition, and thus give rise to one or more secondary disturbances. The great earthquake of Lisbon in 1755 gave rise to secondary shocks in England, Ireland, and probably in many other countries. In the volume containing Physical Observations made in the Antarctic Regions in 1902–3, published under the superintendence of the Royal Society, p. 92, I gave illustrations of secondary earthquakes the genesis of which corresponded in time with the arrival of two particular phases of primary disturbances. That the third phase or the large waves of a seismic disturbance as they travel round the world, causing the crust of the same to rise and fall like a raft on an ocean swell, should give rise to one or more secondary disturbances is not surprising. Farther than this, any of the latter which may be *greater or less* than their parent may in turn become the originator of farther settlements. *One megaseism may therefore cause a relief of seismic strain throughout the world.*"

Of multiple earthquakes a number of illustrations are given. If the interpretation put upon them is correct, it means not only a help to those who wish to analyse seismograms, but a considerable advance in our knowledge of what is taking place beneath our feet. A shake in one place means a shake in many, and it may be added that the *foci* of these are probably in that region where cooling is taking place most rapidly.

In another section of the report we read about the "Synchronism of seismic activity in different regions." For example, it is found that during the last 300 years the times of activity in Italy, although separated from each other by irregular intervals, have varied between five and twenty years, and that these dates of activity in Europe closely corresponded with dates when there had been marked activity in Japan.

Under a section headed "Megaseismic Frequency" we see that between the years 1899 and 1909 there had been 508 world-shaking disturbances in winter months and 468 in summer months, which practically means that there are as many large earthquakes at one period of the year as at any other.

In connection with seismological work, measurements have been made of the deflection of the vertical by the tidal load of the Solent. At Ryde, close to the sea front, it was found that a 10-foot tide caused a deflection of

0·85″. At Bidston, two miles from high-water mark, a similar tide caused a deflection of 0·2″. From these observations inferences have been made bearing on the selection of sites for an observatory, the difference in elasticity of different types of rock, and other matters.

Reference is also made to tidal-load experiments carried out in Pennsylvanian railway tunnels, and to observations made by Mr. J. J. Shaw with horizontal pendulums in collieries in the Midlands.

Following this are catalogues of strong shocks which have occurred in the United States of America, Peru, and Chile, together with epitomes of unpublished notes relating to destructive earthquakes received from Secretaries of State of the Foreign, Colonial, and India Offices. All these will be of use, not only to the seismologist, but also to the man of business.

Lastly, we have a peculiar catalogue, probably the first of its kind. For want of space it only refers to the five years 1899–1903. For these years it gives all the world-shaking earthquakes, whether they originated on land or beneath an ocean. The times at which each disturbance originated, and the latitude and longitude of its epicentre, are specified. Dual or multiple earthquakes are linked by brackets, and the positions of origins are shown on a map. Inasmuch as this catalogue refers to reliefs of strain throughout the whole world, and not simply to earthquakes which have occurred on land surfaces, it seems possible that it may be used as a basis for new investigations.

A note at the end of the report shows that although records obtained on smoked surfaces are extremely good for large disturbances, they fail to record very small movements, which possibly may represent disturbances which were large at their origins.

A communication from Prof. H. H. Turner was a note on the periodigram of earthquake frequency. The conclusion arrived at was that no period of from seven to twenty years existed, or was shown in the materials which he had examined. These materials, however, only referred to large earthquakes which had originated on or near to land surfaces.

Mr. Maxwell Hall communicated a paper on the solar cycle: the Jamaica rainfall and earthquake cycles. The earthquakes observed in Jamaica closely followed the periods of sun-spot activity.

A paper by Mr. Napier Denison, of Victoria, B.C., has been referred to separately (NATURE, November 2).

JOHN MILNE.

SOME RECENT WORK ON SEX.

AT the Portsmouth meeting of the British Association there were several communications to Section D (Zoology) relating to recent work on sex, an account of which is subjoined.

Mr. Geoffrey Smith referred to the theory he put forward at last year's meeting to account for the effect of the parasite Sacculina upon the sexual characters of its host, the crab Inachus, according to which the development of adult female characters in infected crabs of both sexes was held to be due to the production in excess of a yolk or fatty material in the blood similar to that which is stored in the ovary of a normal adult female. Mr. Robson's work (see below) shows clearly that the presence of Sacculina profoundly influences the fat metabolism of its host. Mr. Smith has made observations on the fluctuations in growth of the comb of fowls, which demonstrate the close connection between fat metabolism and the development of the female characters. Measurements show that the combs of hens are continually fluctuating in size, the changes being rapid and between wide limits; a comb may increase 200 per cent. in area in three weeks. It was found that such rapid increase of the comb invariably took place just before a period of egg-laying began. The hen's comb is composed of two walls of fibrous and vascular tissue, between which is a loose core of connective tissue, which at the period of egg-laying becomes infiltrated with fat, and to this cause is due the sudden increase in the mass of the comb. This increase takes place when the ovary is storing up large quantities of yolk, *i.e.* when large amounts of fatty material are being conveyed in the blood to the ovary. Here, then, is another instance of a simultaneous effect upon the ovary and a secondary sexual character brought about by the presence of an excess of fatty material in the blood. Mr. Smith suggested that this case is analogous to that of Inachus infected with Sacculina.

Mr. G. C. Robson described observations, made recently by him in Naples, to test Mr. Smith's theory that Sacculina stimulates the production in the host crab of a yolk-forming substance similar to that developed in the normal female and stored in the ovary at the time of sexual maturity. He examined the blood of the crab Inachus, and especially the lipochromes, which, by reason of their solubility in fat, may be regarded as evidence of the presence of fat. He found a large quantity of fat in the blood of sexually mature females with ripe ovaries, and also that the amount of fat in the blood of infected Inachus was considerably greater than that in the blood of non-infected males and immature females. The blood of moulting individuals of both sexes was also found to have a high fat content, but not so high as in infected examples and breeding females. An increased fat content was also registered in the liver of infected crabs, and there was strong presumption that this was also the case in the breeding female. Mr. Robson also dealt briefly with the changes in colour in the blood lipochromes, and suggested that in all probability the fate of infected crabs is death from starvation, owing to their inability to obtain enough foodstuff of fatty nature for their own immediate needs.

Dr. Cresswell Shearer gave an account of his recent investigations on the archiannelid *Dinophilus gyrociliatus*, collected at Plymouth. This species produces two kinds of eggs, some small, destined to give rise to the small and rudimentary males, others almost six times as large, and also more numerous, which give rise to the large females. The two kinds of eggs are laid together. In a few days the males hatch full-grown and sexually mature, while the females leave the egg in a small and immature condition; just previous to leaving the egg-capsule they are fertilised by the small males. Sections of females at this stage show the sperms collected on the ventral side of the gut at the junction of stomach and intestine, *i.e.* where the future ovary will appear, but as yet no trace of the latter is visible. The ova appear much later, when the female has grown very considerably in size. Shortly after the female germ cells appear, each is seen to be joined by a spermatozoon, the head of which becomes imbedded in, or attached to, the nuclear wall. Ultimately the nucleus of each primitive ovum is composed of two portions, one derived from the spermatozoon, the other from the female cell. These two elements do not fuse, but retain their individuality throughout the various oogonial divisions (about forty to fifty in all). In the majority of these divisions the male and female portions of the nucleus divide equally, so that a similar amount of nuclear material, both male and female, goes into each daughter cell. Now and again, however, the female half of the nucleus seems to divide before the male portion, so that the latter is, as it were, left behind, and is shut off entirely from one of the daughter cells. Of the two resulting daughter cells one has, therefore, the whole of the male part of the original nucleus and its share of the female part, while the other has its share of the female part only. This appears to be the sex-determining factor, for of the two daughter cells the former, which has its share of the female and the whole of the male element, becomes the female egg, while the latter, which has a portion of the female nucleus only, becomes a male egg. Both kinds of eggs, once the sex-determining division has taken place, grow rapidly, absorbing and building up into themselves other immature egg cells with which they come into contact, and in which the divisions of the two portions of the male and female nuclear substance have been equal. The outcome of this process is that the female egg is fertilised, but the male egg is not fertilised in the ordinary sense of the term; but it is impossible to speak of it as really unfertilised, as it has been directly under the influence of the spermatozoon in all the oogonial divisions previous to the sex-determining one. It is only in the late stages, shortly before the female egg is laid, that the two parts of the nucleus fuse beyond recognition.

Prof. C. J. Patten discussed the vernal-plumage changes

in the adolescent blackbird and their correlation with sexual maturity. He held it to be an unsafe procedure to determine the maturity of a bird by its plumage markings; the testes should also be examined macro- and microscopically. He agreed that, as a rule, there is no difficulty in distinguishing the male blackbird in its first spring plumage from the adult of the corresponding time of the year, for the former is usually dark brownish-black with a blackish beak, and the latter jet-black with a yellow beak. But Prof. Patten had specimens in which the yellow coloration of the beak appeared during the first year, coupled with plumage so nearly approaching jet-black that, on general inspection, the bird might pass as being fully mature, the yellow beak being usually regarded as the last sign of maturity. In the birds just mentioned the yellow pigment was developed precociously, and its development outstripped in time the assumption of the true adult plumage, which would not follow until the next year. The testes were 5 mm. long and 2·6 mm. broad, while those of mature birds taken at the same time (the first two weeks in March) were 18 mm. and 10 mm. respectively. In the former there was no sign of spermatogenesis. Prof. Patten concluded that the adolescent blackbirds above described would not have reached maturity until next spring, despite the fact that the beaks were yellow.

THE LAKE VILLAGES IN THE NEIGHBOURHOOD OF GLASTONBURY.[1]

THE second season's exploration of the Meare Lake Village by the Somersetshire Archæological and Natural History Society began on June 5, and was continued for three weeks under the joint supervision of Messrs. A. Bulleid and H. St. George Gray. The ground excavated was situated in the same part of the village, and was directly continuous with last year's work.

The digging included the examination of the remaining portion of Dwelling-mound VII., the whole of Mound VIII., and portions of Mounds IX., X., and XI.

With reference to the construction of the above mounds, two, *i.e.* Mounds VIII. and IX., had special points of interest, and call for mention here. Taken as a whole, however, this part of the work has been up to the present time somewhat disappointing, as little additional information has been gained regarding the structure generally apart from that already acquired at the Glastonbury Lake Village.

Mound VIII. was of medium size, consisting of five floors and situated north-east of Mound VII. No hearth was discovered associated with the two uppermost floors, which were separated with much difficulty throughout. An interesting series of eight superimposed baked clay hearths was, however, found belonging to Floors iii., iv., and v., surrounded by thick layers of fire-ash. The hearths varied from 2 feet 6 inches to 5 feet 3 inches in diameter.

Mound IX. was of large size, consisting, apparently, of two floors, and was only partially examined. Below the clay was a thick layer of black earth composed of charcoal, fire-ash, and débris containing quantities of bones of animals and fragments of pottery. Under the black earth a well-preserved platform of timber was disclosed, bordered by the remains of the wattled wall of a circular dwelling. This timber was chiefly arranged in a north-east and south-west direction, and by far the larger number of the wall-posts were made of squared oak, a feature not hitherto noticed in the dwellings previously examined.

The relics discovered this season were scarcely so numerous as last year. A summary of them is appended.

Bone.—The bone objects were not very numerous. The most interesting specimen is a smooth pin without head, having a long recess, or notch, along the middle of the shaft. A similar object was found with late Celtic remains on Ham Hill, South Somerset (Taunton Museum), and another on the Roman site at Iwerne, Dorset (Pitt-Rivers Museum, Farnham, Dorset). The other specimens include two tibiæ of horse (sawn and perforated), two large polishing-bones, pins, a dress-fastener, part of a drill-bow, and two objects of worked bird-bone.

Worked Carpal and Tarsal Bones of Sheep or Goat.—A large number of "bobbins" and other objects, showing signs of considerable use, have been found, especially in Mound VII., where so many weaving appliances were discovered. Many of these bones are perforated in different directions; others have transverse markings, some deeply grooved and very smooth.

Worked Shoulder-blades of Ox and Horse.—At the end of last season no fewer than thirty-two of these objects had been found, all in Mound VII. Four more were collected from the same dwelling this year, and two others in adjacent mounds. Two of those found in Mound VII. are ornamented with large examples of the dot-and-circle pattern. In all instances the bones are smooth, and the longitudinal spine had been cut down considerably. Many of them are perforated at the articular end (probably for suspension). They have been found where weaving implements are abundant, but their use remains to be explained.

Crucibles.—Fragments of two found this year.

Bronze.—Fifteen objects of this material were uncovered this year, but no fibulæ are included. There are three finger-rings, one ornamented by a cable pattern, two rivets (one of a new type), an awl, three thin moulded bosses, part of a belt-fastener, and a large part of the bordering of a perishable scabbard, including the bulbous chape. Perhaps the most interesting remains of bronze is a pair of pins with disc-shaped heads and arched stems.

Flint.—In addition to a number of flakes, a scraper and two or three finely worked knives have been found.

Glass and other Beads.—The beads are numerous and varied. Nine were found last season; eighteen specimens this year. The collection includes two polished bone ring-beads. Six of the beads are of a yellow opaque glass and two pale blue (also opaque). One of the finest specimens is a ring-bead of clear sea-green glass, and two are dark blue. A small blue bead is ornamented round the sides by a continuous wave pattern; two globular beads of clear white glass are ornamented in yellow, one by a spiral device, the other by a herring-bone pattern. The smallest bead is little more than one-eighth of an inch in diameter.

Antler.—The numbered objects of this material have now reached the total of seventy-three, twenty-four being found this season, including three antlers of roe-deer, one bearing knife-cuts, another being shaped as a knife-handle. Nothing of exceptional interest has been found this season, many being pieces of cut antler impossible to name. The two hammers found have not been perforated for fitting handles. Several examples of the so-called "cheek-pieces," perhaps used in connection with the bridles and bits of horses, have been found; but the precise use of many of these objects is very doubtful, and their shaping and perforating vary very considerably.

Weaving-combs of Antler.—Again we have a fine series, bringing the former number of twenty-one up to a total of thirty-five. Mound VII., which must have been a weaving establishment, contributes no fewer than twenty-nine of the number. No dwelling in the Glastonbury Lake Village produced more than nine of these combs. One example is dentated at both ends with twelve and thirteen teeth respectively. The largest, having ten teeth, is 7¾ inches long. Several of them are ornamented with transverse and oblique lines, and one, at least, with dots and circles.

Iron.—The objects of iron are mostly fragmentary, and much corroded, as usual. The "finds" include a chisel, knife, file, and an awl in its handle of antler; also an earth-anvil. The latter was found on the top floor of a mound, and only a foot deep below the flood-soil, through which, owing to its weight, it may probably have sunk subsequently to the occupation of the village.

Kimmeridge Shale.—Objects of this material have this season been increased from twelve to twenty-one, and they are more numerous than in the neighbouring village of Glastonbury. These objects are parts of lathe-turned arm-

[1] Report presented at the Portsmouth meeting of the British Association (Section H) of the committee appointed to investigate the lake villages in the neighbourhood of Glastonbury in connection with a committee of the Somersetshire Archæological and Natural History Society. (Drawn up by Messrs. Arthur Bulleid and H. St. George Gray, the directors of the excavations.)

lets, with three exceptions, viz. a set of three roughly cut heavy rings, which may have been used in connection with horse-harness. In section, one of the armlets (half) measures no fewer than 21 mm. by 16 mm.

Lead and Tin.—Last season three net-sinkers of lead were found, to which one has been added this year. The first object of tin has been found, viz. a small whorl (? bead) ornamented with encircling lines of small punch-marks.

Querns.—Compared with the Glastonbury Lake Village these are plentiful at Meare; but the circular rotary querns are rare as compared with the saddle-shaped specimens, of which some well-preserved examples have been found.

Other Stone Objects.—Parts of circular blocks of stone have been found, slightly recessed on one face and having a narrow rim; they show signs of intense heat, and may be parts of moulds for casting thin bronze. A large assortment of stone hammers and whetstones has been found.

Sling Bullets.—Several of the baked clay sling bullets typical of the period have been collected. Under the clay floors of the mounds three groups of selected ovoid stones were discovered, the numbers being 99, 182, and 347 respectively.

Spindle-whorls.—The former number of twenty-three has this season been increased to forty-three. Most of them are formed from discs of lias; a few are of baked clay, two being very large.

Pottery.—Shards of pottery have been very numerous—some three or four hundredweights. All of them have been scrubbed and preserved, being sorted under the numbers of the dwellings. Several complete pots may probably be built up some day. The proportion of ornamented fragments is high as compared with those from the neighbouring village, and a great many new and highly ornate designs have been added to the collection. Very little ornamented pottery was discovered in the deepest layers, and much of it bearing typical late Celtic designs was found just under the flood-soil. The coarser plain pots were generally found in the black earth and brushwood below the clay floors.

Human Remains.—Two pieces of skull and one bicuspid tooth.

Animal Remains.—Found abundantly. The perforated boars' tusks and canine teeth of large dog were no doubt used as personal ornament. The enormous number of bones of young animals indicates that the inhabitants of this marsh village must have been great meat-eaters. The remains of beaver and otter are frequently met with, and also a considerable number of bird-bones.

LEGISLATION AGAINST INSECT PESTS AND PLANT DISEASES.[1]

THE effort to secure national legislation to keep out new and dangerous insect pests or plant diseases which may be brought in with imported nursery stock has been actively favoured by the U.S. Department of Agriculture, just as the department in the past has promoted and secured legislation enabling it to exclude from the country diseased animals or to quarantine and stamp out animal diseases whenever such have appeared. In the case of domestic animals, the exercise of these powers has brought enormous benefit, and has worked entirely satisfactorily to the livestock industry. It is reasonable to believe that like benefits to fruit and forest interests, including the nursery business, will undoubtedly come from similar legislation to exclude insect pests and plant diseases.

The immediate danger which led to the recent effort to secure legislation was the discovery in 1909 of the abundant importation and wide distribution into the United States of nursery stock infested with brown-tail moth nests and occasional egg masses of the gipsy moth. During the years 1909 and 1910 such infested stock was carried into twenty-two States, covering the country from the Atlantic seaboard to the Rocky Mountains. During the first of these years no fewer than 7000 winter nests of the brown-tail moth, containing approximately 3,000,000 larvæ, were found in shipments into New York State alone—seed material enough to infest the whole United States within a few years. During the second of these years 617 of these nests were found on nursery stock shipped into the State of Ohio, and a much larger number, approximately the same as the year previous, were again sent into New York. Smaller numbers of these nests, proportioned to the amount of nursery stock received, were sent into other States east of the Rocky Mountains during both these years. Fewer brown-tail moth nests were received during the season just ended (1910–11), owing to the agitation in this country and more strict supervision by foreign Governments.

[1] From Circular No. 37 of the U.S. Department of Agriculture.

So far as possible, this stock, as voluntarily reported by customs officers and railroads, has been examined and the brown-tail nests removed or destroyed by State authorities, or, where these were not available, by agents of the Bureau of Entomology of the United States Department of Agriculture. Undoubtedly many shipments have not been reported or examined, and it is quite probable that local infestation has already started at different interior points. The history of both the gipsy and brown-tail moths in New England shows that these insects may be present for several years without being noticed, slowly gain headway, and then suddenly develop their full power of destructiveness.

It is scarcely necessary to comment on the danger from the careless introduction and wide distribution of these two orchard and forest pests. In a limited district in New England more than a million dollars a year have been spent for a long period in a mere effort to control these two insects, and the General Government is now appropriating three hundred thousand dollars annually to endeavour to clear them from the border of main highways and thus check their spread. These expenditures do not take into account the actual damage done, but they do serve as a measure of the danger to the whole country from the recent distribution of these two insects on imported nursery stock.

As further illustrations of the constant risk from lack of legislation may be mentioned two very recently introduced insects which will undoubtedly prove very expensive pests in future years. The European alfalfa leaf-weevil, on the authority of the entomologist of the Utah Experiment Station, Mr. Titus, was probably brought into Utah on packing of nursery stock or other merchandise from Europe. This leaf-weevil has already destroyed much of the value of the important alfalfa crop of Utah, and is spreading into adjacent States. The other illustration is the Oriental cotton scale (*Pulvinaria psidii*), probably the worst scale pest of citrus and other subtropical plants in southern Asia. This scale insect has recently been introduced into Florida on imported stock, and is already well established there.

New plant diseases, against the entrance of which there is at present no bar, may even more seriously jeopardise the farm, orchard, and forest products of this country. Imported potatoes from Newfoundland are now bringing in the potato wart disease, which, wherever it has been introduced in Europe, and also in Newfoundland, puts a stop to potato culture. The importation of white-pine seedlings is now bringing in the European white-pine blister rust, which, if established and disseminated, will destroy much of the value of our white-pine forests. Absolute quarantine against these two plant diseases is the only means of keeping them out. The chestnut disease, now practically shown to have been introduced on trees imported from Japan, illustrates what may quickly happen from such unchecked introductions.

More than half of the important insect enemies and plant diseases now established in the United States have been brought in on imported nursery stock, and new insect enemies and new diseases are being thus introduced every year. Twenty different insect pests, new to the United States, some of them very formidable in the Old World, have been intercepted in the inspections of the imported material by this department this year, and this does not include the introduction of brown-tail moth nests and other European pests with imported seedling stock.

A properly enforced quarantine and inspection law in the past would have excluded many, if not most, of the

foreign insect enemies and plant diseases which are now levying an enormous annual tax, amounting to several hundred million dollars, on the products of the farms and orchards of the United States.

In spite of the many pests which have already gained foothold, and the control of which will be a permanent annual charge on production, there remain many other insect pests and plant diseases with equal capacity for harm which, fortunately, have not yet come in; and it is to protect from these new dangers that legislation is now sought, not with the intention of prohibiting the trade in imported stock, but to throw such safeguards around it as will most protect both the importers and the subsequent purchasers of such stock.

The insect pests and plant diseases that have come in are probably here for all time, but certainly no reasonable objection can be made to the effort to safeguard the future. The conscientious importer will be benefited, and the home producers, the dealers, and all the great fruit and forest interests will be protected by suitable inspection and quarantine legislation.

The San Jose scale had become established in California on stock introduced from China about 1870, and was known to be one of the most serious of orchard pests. With proper supervision and quarantine it undoubtedly could have been limited to the Pacific Coast indefinitely. A quite unimportant importation of stock from California by a prominent Missouri nurseryman in the early 'nineties established this scale in several eastern nurseries, and this led to the first concerted effort to obtain a national quarantine and inspection law. The failure to reach an agreement among the nurserymen, fruit-growers, and entomologists as to suitable legislation prevented anything coming from this effort, although several Bills were introduced in Congress from time to time. In the meantime, the San José scale became so widely distributed by transportation on nursery stock that quarantine against this insect was no longer practicable; and the United States is now being taxed, and probably will be for all time, many million dollars annually because there was no law under which strong hold could have been taken of this danger at the outset.

As elsewhere noted, the recent effort to secure legislation followed the entry and wide distribution in the United States of brown-tail moth nests on nursery stock, chiefly from northern France. The discovery about the same time of the entry of the potato wart disease from Newfoundland, and the white-pine blister rust, chiefly from one district in Germany, greatly emphasised the immediate need for Federal control.

In the measure now before Congress, inspection of imported nursery stock is left to the different States instead of being undertaken by the Federal Government. A complete system of notification is provided for, however, both through the requirement of a permit and by subsequent advices to be given by the customs offices, the broker or first receiver of the stock, and the common carrier transporting it.

The first clause of the Bill is as follows:—It shall be unlawful for any person, firm, or corporation to import or offer for entry into the United States from any foreign country any nursery stock unless and until a permit shall have been issued therefor by the Secretary of Agriculture, under such conditions and regulations as the said secretary may prescribe, and unless such nursery stock shall be accompanied by a certificate of inspection in manner and form as required by the Secretary of Agriculture from the proper official of the country from which the importation is made to the effect that the stock has been inspected and found free from injurious plant diseases and insect pests: *Provided*, That this section shall not be construed as applying to plants or plant products solely intended for and adapted to use as food, but to nursery stock or other plants or plant products for propagation: *Provided further*, That nursery stock may be imported for experimental or scientific purposes, without the certificate of inspection or the permit of the Secretary of Agriculture hereinbefore required, upon such conditions and under such regulations as the Secretary of Agriculture may prescribe: *And provided further*, That nursery stock imported from countries where no official system of inspection for such stock is maintained, may be admitted upon such conditions and under such regulations as the Secretary of Agriculture may prescribe.

One clause in the Bill makes provision for quarantining foreign districts or particular plant products in foreign districts to exclude diseases or insect enemies which cannot otherwise be kept out. This is the provision which has been most objected to by importing nurserymen, and especially by importers who have invested in foreign nursery enterprises in France. It is not the intention to apply this section except in the case of diseases or other dangers which cannot be kept out by inspection or disinfection; in other words, at present it would apply only, so far as is known, to the potato wart disease and the white-pine blister rust. Another clause provides for quarantining districts within the United States where new diseases or insect enemies have gained a foothold until such districts have been freed from such disease or insects.

PRACTICAL STANDARDS FOR ELECTRICAL MEASUREMENT.[1]

THE committee has to regret the death since the last meeting of the association of Dr. G. Johnstone Stoney, F.R.S. He had been a member since 1861, and up to a few years since continued his active interest in the work. In its earlier stages his skill in definition and his admirable choice of nomenclature had proved invaluable to the committee. The collected reports which are to be issued shortly will indicate how large a share in the establishment of the C.G.S. system of units is due to him.

Republication of Reports.—The republication of the reports is not yet completed, but this should be done within the present year. The proofs of the reports from 1862 to 1883 have been finally revised, and the remaining proofs will soon be ready.

Lorenz Apparatus.—The progress made has been satisfactory. Preliminary experiments have shown that the apparatus is uninfluenced by changes in the earth's magnetic field, and that the thermal E.M.F.s at the brushes on the two discs very nearly balance. With the form of brush in use at present there are sudden changes in the difference of the thermal E.M.F.s amounting to 2×10^{-7} volt, and it may be difficult entirely to eliminate these. With other forms of brushes, *e.g.* those made of gauze, the difference was often 1000 times as great. It was this difficulty which led Lord Rayleigh in 1883 to amalgamate the edge of the disc, and as a further improvement Prof. Viriamu Jones and Prof. Ayrton used mercury jets instead of brushes. Since in the present apparatus the changes are only 1 in 10,000 of the difference of potential produced in one arrangement of the brushes and fewer for a second arrangement, it is hoped that mercury contacts will not be necessary. Further experiments will be made in order to obtain greater perfection, if such is possible.

Resistance Standards.—The construction of new mercury standards of resistance in accordance with the specification of the London Conference is being proceeded with, and some of the standards will be completed this year. Similar work is in progress in France, in Germany, in Austria, and in the United States. In the last-named country four standards have had all their constants determined, and the resistance unit so obtained is in very close agreement with that obtained from the old National Physical Laboratory standards.

In the committee's report for 1908 it was shown that many manganin resistance coils—some of which were purchased by the committee in 1895—were very changeable in resistance, and in consequence frequent comparison with mercury standards was necessary. In 1908 it was shown at the Bureau of Standards, and confirmed at the National Physical Laboratory and at the Reichsanstalt, that these changes were largely due to the effect of moisture on the shellac covering the wire. To eliminate this source of trouble many of the coils were hermetically sealed in 1909,

[1] Report presented at the Portsmouth meeting of the British Association by the Committee on Experiments for Improving the Construction of Practical Standards for Electrical Measurements.—Lord Rayleigh (chairman), Dr. R. T. Glazebrook (secretary).

and it is satisfactory to record that they are now much more constant. The importance of this hermetical sealing is so great when manganin resistances are to be sent to such places as cable stations in the tropics that the attention of instrument manufacturers is directed to the matter. Standard coils are readily sealed, and boxes of coils may be sealed in metal cases. The following figures for standard coils of manganin show the advantage of hermetical sealing :—

Nominal value		100 ohms		1,000 ohms	10,000 ohms
		No. 2450	No 740	No. 2449	No. 2448
Open coils	Oct. 1903	99·9959	1,000·153	1,000·012	10,000·24
	,, 1904	100·0002	0·172	0·244	2·40
	,, 1905	0·0048	0·218	0·494	3·57
	,, 1906	0·0092	0·248	0·668	3·82
	,, 1907	0·0132	0·266	0·814	3·74
	,, 1908	0·0288	0·302	1·130	3·85
Hermetically sealed in paraffin oil.	June 1909	0·0369	0·365	1·046	5·53
	,, 1910	0·0384	0·357	1·075	5·55
	,, 1911	0·0399	0·359	1·069	5·61

It will be noted that the changes during the last three years are very small.

Silver Voltameter and Standard Cell.—Although the actions which take place when a current passes through a solution of silver nitrate, as in a silver voltameter, are now well understood, the effects of septa—such as silk, filter paper, and porous porcelain—are by no means clear, and experiments have, therefore, been made to decide whether any septum at all should be used in a voltameter. Such experiments were suggested at the Washington meeting in 1910. The results of the experiments made at the National Physical Laboratory indicate that a septum of any kind is usually a source of trouble, and may produce secondary reactions during the electrolysis which affect the weight of the silver deposit. Fortunately, voltameters have been designed which render a septum unnecessary; and these may be useful, not only in precise current measurements with the silver voltameter, but for the deposition of metals other than silver.

The reproducibility and constancy of the Western normal cell are still being carefully examined. The chief anomaly is the hysteresis effect mentioned in last year's report; for this effect we have no explanation, although one is much needed, as probably it would enable cells to be made so as to remain even more constant in E.M.F. than at present. It is necessary to point out that while the effect is called a hysteresis one, the E.M.F. does not lag behind the temperature. Briefly put, with ascending temperatures the E.M.F. changes in close agreement with the temperature–E.M.F. formula, but with descending temperatures the E.M.F. changes too rapidly, corresponding to values at temperatures lower than the temperature of the cell by from 3° to 15°.

The committee had hoped to make this the last report; but in view of the fact that the republication is not complete, it asks for reappointment, with Lord Rayleigh as chairman and Dr. R. T. Glazebrook as secretary.

THE LOCH LEVEN WATER-POWER WORKS.[1]

THE Loch Leven Water-power Acts were obtained in 1901 and 1904, authorising the construction of works to utilise the rainfall of the western slope of Rannoch Moor for power for industrial purposes.

The catchment-area for the Loch Leven works is the basin of the River Blackwater, and is 55 square miles in extent, lying between Lochs Treig, Ossian and Rannoch, and Glen Coe. Rain-gauges established in 1905 and 1906 have given average readings of more than 70 inches for the Blackwater basin and 80 inches for Kinlochleven. No compensation-water had to be supplied, this feature greatly increasing the available power. The site of the reservoir is favourably contoured for storage purposes, and the full reservoir is about 7½ miles in length and half a mile in breadth. Its greatest depth is 75 feet, and it impounds more than 20,000 million gallons of water. The Blackwater dam is 3112 feet in length, with a maximum height of 86 feet, its top surface being 1068 feet above Ordnance datum. About half its length is formed as a waste-weir in six horizontal steps of 6 inches each.

The foundation is of an exceptionally sound character; only a few feet of the surface beds had to be removed to obtain a satisfactory foundation. The dam is built of large blocks of stone embedded in a matrix of ordinary concrete, with fine concrete facework. The valve-tower contains the six valves of the three draw-off pipes, the spindles being carried up to the valve-house above top water-level. The draw-off pipes lead to the upper penstock chamber, whence the water is delivered over a measuring weir into the conduit. Water is conveyed to the pipe-track by this conduit, which is 3½ miles in length; it is of square section, 8 feet by 8 feet, and is laid to a general gradient of 1 in 1000.

Along the route of the conduit and above the same lies a catchment-area of 3½ square miles, with a rainfall of about 75 inches, the greater part of which is drained by three streams. These have been laid under contribution by collecting their water and turning it into the conduit. Electrical transmitters and recorders indicate to the valve-keepers at the lower penstock chamber the changes taking place in the contribution of the side streams, enabling them to take advantage of the extra water and reduce the draw-off from the reservoir, thus storing an equivalent quantity of water in the reservoir. The conduit discharges its water into the lower penstock chamber, of about 300,000 gallons capacity, where it is measured and delivered to the pipes as required.

From the penstock chamber water is conveyed to the power-house in six welded steel pipes of 39 inches diameter. The track is 1¼ miles in length, and the fall of 935 feet yields a normal static pressure of 406 lb. per square inch. Water is distributed from the six main pipes to the various turbines by a system of pipes comprising two omnibus pipes and six feeders, all of 39 inches diameter. Each "bus" pipe with its three feeders forms one complete system, the two systems being at different levels to enable branches to cross. One branch from each bus pipe feeds each turbine. At the top of the pipe-track, immediately below the penstock chamber, automatic cut-off valves have been installed to stop the flow of water in the event of a burst occurring on the main pipe-lines.

The works described have cost about 600,000*l.*, and are now the property of the British Aluminium Company. The construction was begun in August, 1905, and the factory commenced working in February, 1909.

As regards the plant erected in the power-house at Kinlochleven, the aggregate power installed is 30,660 horse-power at the generator couplings, the generators being capable of a maximum output of 21,088 kilowatts. Nine main units and two exciter units are erected, each unit consisting of a turbine and two generators. The main turbines are of the Pelton-wheel type, with two water-jets, and are designed to give 3200 B.H.P. as a maximum; each drives two generators coupled in parallel, and having an output up to 2200 kilowatts together. The two small exciter units are also of the Pelton-wheel type, each driving a pair of generators on one shaft. These consist of an exciter and lighting machine, capable of giving an output up to 550 kilowatts, and a traction machine up to 94 kilowatts capacity.

Efficiency and governor tests were carried out on the main units, and governor tests on the exciter units. The results obtained showed that the turbines did not quite reach their anticipated output, and that their efficiency was slightly below that guaranteed by the makers. The efficiency was improved about 2 per cent. by increasing the area of the lower jet, but keeping the top jet of the original size, and by this alteration the turbines were enabled to give the specified output at the guaranteed efficiency.

It was found during the tests that the generators were liable to flash over if the voltage increased excessively, and

[1] From abstracts of two papers: (1) The Loch Leven Water-power Works, by A. H. Roberts; and (2) The Hydro-electric Plant in the British Aluminium Company's Factory at Kinlochleven, by F. B. Sonnenschein, read at the meeting of the Institution of Civil Engineers on November 14.

that they were also liable to flash over if a circulating current flowed round the two armatures of the dynamos on the same shaft running in parallel, when load was thrown off. An electrical protective device was therefore designed and fitted to each pair of generators, which automatically breaks the field-circuit when either of these two conditions arises.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The opponents of the statute allowing exemption from Greek in the case of candidates for honours in mathematics and natural science, which is to be submitted to Convocation on November 28, have put out a circular in which their objections are stated. One of their principal contentions is that when Greek becomes optional at the universities, the teaching of that language will be given up at many of the smaller schools throughout the country, and that in consequence many boys who are capable of profiting by the study will be deprived of the opportunity of instruction in Greek during their school career. The authors of the document say that while deprecating the abolition of compulsory Greek, they are favourable to a reform in existing methods of teaching and examination.

PROF. JOHN PERRY, F.R.S., will deliver an address at the opening of the new mechanical engineering laboratory of the Municipal Technical Institute, Belfast, on Friday, November 24.

MR. S. MANGHAM, formerly Frank Smart student in botany at Cambridge, has been appointed lecturer in botany at Armstrong College (University of Durham). Lord Grey has accepted the office of president of the college.

SUBSCRIPTIONS for 30,000*l.* to meet the conditional pledge of 10,000*l.* from the General Education Board have been received by Middlebury College. It is stated in *Science* that one-half of the fund will be reserved for general endowment.

AT the Sir John Cass Technical Institute, Aldgate, E.C., on Wednesday, November 29, Mr. H. Livingstone Sulman, president of the Institution of Mining and Metallurgy, will distribute the prizes and certificates gained by students during the past session.

THE Ontario correspondent of *The Times* announced on November 19 that the first day's subscriptions from Montreal to the million-dollar fund for McGill University reached 66,735*l.*, including 10,000*l.* telegraphed from London by Dr. James Douglas, who was formerly professor of chemistry at Morrin College, Quebec.

THE fourth annual dinner of old students of the Royal College of Science, London, is to be held at the Imperial College Union, Prince Consort Road, South Kensington, on December 13, at 7.30 p.m. The sixth annual dinner of the Finsbury Technical College Old Students' Association is to be held at the Trocadero Restaurant on December 9, at 7.30 p.m.

MRS. C. KAYLER has given 1000*l.* to University College Hospital to found and endow a lectureship in memory of her father, the late Dr. Sydney Ringer, F.R.S., formerly consulting physician to the hospital. The lecturer will be selected every two years, and will take as the basis of his lecture original research carried out by him in the physiological or pharmacological laboratories of University College or in University College Hospital Medical School.

THE death of Lady Reichel, which occurred at Bangor the next day after the degree ceremony noted in last week's NATURE, will be felt as a loss by all those interested in higher education in Wales. As wife of the principal of the University College of North Wales, Lady Reichel, while holding no important official position, had by her personality and influence rendered indirect services, of the value of which it would be difficult to form an adequate estimate, to the cause of education.

THE Board of Agriculture and Fisheries has awarded the following research scholarships in agricultural science:—P. G. Bailey (Cambridge), J. Clayton (Cambridge), J. T. Edwards, E. T. Halnan (Cambridge), J. Hammond (Cambridge), J. A. Hanley, G. E. Johnson (Birmingham), C. G. P. Laidlaw (Cambridge), A. E. Lechmere (Bristol), J. W. Lesley (Cambridge), A. Neville (London), and G. H. Spinks (Cambridge). These scholarships have been established in connection with the scheme for the promotion of scientific research in agriculture, for the purposes of which the Treasury has sanctioned a grant to the Board from the development fund. The scholarships, which are of the annual value of 150*l.*, and are tenable for three years, have been established in order to train promising students, under suitable supervision, with a view to their contributing to the development of agriculture, either by carrying out independent research or by acting in an advisory capacity to agriculturists.

AT the annual meeting of the Mathematical Association, to be held in January next, the following papers will be presented:—What should be omitted in arithmetic? J. B. Sachs; mathematical work in training colleges, Rev. E. M. Radford; some unrealised possibilities in mathematical education, G. St. L. Carson; the work of the International Commission on mathematical teaching, C. Godfrey; the calculus as a school subject, C. V. Durell. In addition the following subjects for discussion are proposed:—A recognised universal sequence of propositions in geometry for schools, H. G. Mayo; the educational value of the mathematics examination, E. F. Edwards; the logic of algebra, whether or where we should teach it, S. Andrade; the treatment of parallel lines, Rev. J. J. Milne; differentiation and integration as purely algebraic processes, W. F. Sheppard; is the educational prestige of mathematics lessening? G. St. L. Carson; the elementary teaching of the calculus, Rev. E. M. Radford; first lessons in algebra, W. A. Richardson.

IN connection with the work of the General Education Board of the United States, we learn from *Science* that conditional appropriations amounting to 127,000*l.* have been granted to six colleges and universities by the board of trustees. Applications from twenty-four institutions were presented. From this list the board selected six, among which is distributed conditionally the available funds as follows:—to Bucknell University, Lewisburg, Pa., 7000*l.* towards 32,000*l.*; to Earlham College, Richmond, Ind., 15,000*l.* towards 80,000*l.*; to Furman University, Greenville, S.C., 5000*l.* towards 20,000*l.*; to Grinnell College, Grinnell, Ia., 20,000*l.* towards 100,000*l.*; to Smith College, 40,000*l.* towards 200,000*l.*; to Southern Methodist University, Dallas, Tex., 40,000*l.* towards 200,000*l.* During the meeting attention was directed to the fact that since Mr. Rockefeller made his first contribution to the board for the promotion of higher education, contributions have been made to ninety-one institutions, amounting to 1,525,000*l.*, towards a total of 7,182,000*l.* Fifty-one institutions to which the board has made conditional contributions have completed the subscriptions for the supplemental sums required, and to these institutions the board has already paid 700,000*l.* in cash. As a result of the campaigns made by these fifty-one institutions, their assets have been increased by more than 3,800,000*l.* Their student bodies have increased by 2047, 183 new professors have been employed, and the annual payment to professors in these fifty-one institutions has been increased 84,300*l.*

As indicative of the growing appreciation of the value of higher education in science and technology among the native aristocracy of India, the following remarks, recorded in *The Pioneer Mail*, from a speech at an educational conference by the Nawab Bahadur of Dacca are interesting. Supporting the statement that "the want of a combined course of education has to answer for the degraded state of our community," he said:—"It is none the less due also to our utter indifference to technical, industrial, agricultural, and commercial education. If we had developed our industrial resources, improved our agriculture, and learnt business, hunger would not have peeped in our peasants' houses. Our interests would not have clashed had we not flocked to the general line of education only, but turned to other branches for which we might have special aptitude and be better fitted. The inevitable consequences of this wanton neglect of these branches have been the cramming of all offices and pro-

essions, and the poverty of the people. Our trades and ndustries are dying out, and prosperity is out of the ques- ion if we do not revive them. Our lands are immense reasures, for gold is buried there if we only render them roductive. We cannot grow one quarter of what they o in the civilised countries of Europe and America for the ame area. There is immense room for improvement in ll these directions, especially in agriculture; and although here has been a general awakening, and Government has een kindly lending its help, our capitalists do not come orward to invest money in such undertakings." He con- luded:—"I would most earnestly appeal to you to try o create an indomitable passion for education in your iends, relatives, and fellow-brethren, without which our ociferation for the regeneration of our community is but rying in the wilderness."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 16.—Sir Archibald Geikie, .C.B., president, in the chair.—Sir E. Ray **Lankester**: he discovery of a novel type of flint implements below e base of the Reg Crag of Suffolk, &c. (1) Flint imple- ents of human manufacture have been discovered by Mr. . Reid Moir, of Ipswich, in the detritus beds at the base f the Red Crag in Suffolk, and by Mr. W. G. Clarke at e base of the Norwich Crag in Norfolk. (2) These nplements are of a novel type—the "rostro-carinate," or eagle's beak"—but include also scrapers, hammers, and rge one-sided picks. They do not include any forms re- embling the Chellian and Acheuilian ovate implements. he sub-crag type (rostro-carinate) is essentially com- ressed from side to side. The Chellian and Acheuilian nd Moustierian types are essentially depressed or flattened ke a leaf. (3) They were manufactured at a period revious to one of severe glaciation, which set in before e lowest beds of the Red Crag and Norwich Crag were eposited, and characterise a phase of human development arlier than any hitherto known by equally indisputable idence. (4) The rostro-carinate implements were not nprobably used for dressing and smoothing the skins of nimals. (5) On the land surface from parts of which ese implements were moved into the detritus beds at the ase of the East Anglian "Crags," similar implements re- ained, which were embedded in the subsequent deposits the Glacial period, and have been found in a few isolated stances in mid-glacial sands and Boulder Clay. (6) The ed Crag is commonly regarded as of greater geologic e than its proper fauna would indicate. Its mammalian ssils are derivatives of an earlier age, and the few olluscs of Pliocene character found in its earlier layers e lingering survivors from a warmer condition of the a. They became extinct at the early onset of the con- tions proper to the Red Crag sea. The Red Crag should grouped with the Pleistocene rather than with the liocene series. (7) The race of men who manufactured e sub-crag flint implements probably lived on the land rface not remote from the sea during the period of the oralline Crag, which was characterised by a warmer imate than that of the Red Crag, and may justly be re- rded as marking the close of Pliocene conditions in this rt of Europe. The land barrier joining Britain to andinavia, which had kept the southern part of what now the North Sea from access of cold northern waters er since the earliest Tertiary period, disappeared at the ginning of the deposition of the Red Crag. (8) If these opositions are justified, it remains a question for later quiry whether the men who made the sub-crag imple- ents were of greater antiquity than those who made the plements (so-called eoliths) of the high plateau gravels Kent, or than those recognised by some archæologists makers of roughly chipped flints found in other locali- s, but not hitherto generally admitted as of human orkmanship. (9) In any case, the implements from the b-crag beds in East Anglia are of special and very tinct type, and cannot be associated with any known om any other locality.—Prof. E. W. **MacBride**: Studies heredity. I.—The effects of crossing the sea-urchins *hinus esculentus* and *Echinocardium cordatum*. Many ologists have investigated the question as to how far paternal and maternal characters are transmitted when different species of echinoderms are crossed, and have arrived at inconclusive and contradictory results. The reasons for the unsatisfactory results of their investigation are largely to be found in incomplete study of the normal development of the species to be crossed, and consequent dependence being placed upon characters which are either slightly marked or variable in the normal larva. There are two cases where the larvæ are distinguishable from one another by sharply marked characters, about the presence or absence of which there can be no possible doubt. The first case, that of the late larvæ of *Echinus miliaris* and *E. esculentus*, which are distinguished by the number of ciliated epaulettes, has been investigated by De Morgan and Shearer, who find that the hybrid in all cases shows purely maternal characters. The second case, that of the larvæ of *Echinus esculentus* and *Echinocardium cordatum*, the larvæ of which are distinguished by the presence of an aboral spike in those of the latter species and its absence in those of the former, forms the subject of this paper. It is shown that the eggs of Echinocardium fertilised by the sperm of Echinus give rise to hybrids which show the paternal character in the total absence of the spike, whilst the eggs of Echinus fertilised by the sperm of Echinocardium form a fertilisation membrane, but then undergo cytolysis. Loeb and his pupils have been able to fertilise the egg of sea-urchins with the sperm of animals belonging to different classes of animals. In all these cases the larvæ are a purely maternal type. It is, therefore, startling to find that when the eggs of Echino- cardium are fertilised with the sperm of a creature so far apart in systematic position as Echinus the paternal character should be so clearly marked in the hybrid.—Prof. W. M. **Thornton**: The influence of ionised air on bacteria.—Dr. T. Graham **Brown**: The intrinsic factors in the act of progression in the mammal. (1) By means of a stimulus (namely, section of the spinal cord) central in application, although remote from the local centre, the act of progression may be induced in muscles de-afferented by the cutting of their appropriate posterior spinal roots. It occurs thus after all the muscles of both hind limbs have been de-afferented, and all but the recording pair have been put out of action by motor paralysis. (2) The act of progression as exhibited by these muscles, and thus induced, scarcely differs, if indeed it differs at all, from the act similarly induced when the afferent parts of the recording muscles have not been broken. (3) In either case the reaction, as evidenced in movement at the ankle- joint, shows three periods. In the first the record is characterised by a state chiefly of maintained flexion. In the last there is a state characterised by maintained extension. Intermediate between these there is a period of "balance," in which the movements of progression are most perfect. (4) *The rhythmic sequence of the act of progression is consequently determined by phasic changes innate in the local centres, and these phases are not essentially caused by peripheral stimuli.* (5) *The proprio- ceptive stimuli which are generated by the contraction of muscles taking part in the act (when the appropriate posterior spinal roots are intact) play a regulating, and not an intrinsic, part in the act. Their chief importance may be in the grading of the individual component move- ments to the temporary exigencies of the environment.*— Dr. J. L. **Jona**: The refractive indices of the eye media of some Australian animals.—S. G. **Paine**: The permea- bility of the yeast cell.—G. A. **Buckmaster** and J. A. **Gardner**: Ventilation of the lung in chloroform narcosis. The authors give a number of plethysmographic tracings to show the lung-ventilation during chloroform anæsthesia with different percentages of chloroform and ether, and also analyses of the blood gases. They show that with un- impeded respiration under anæsthesia by chloroform given at a slight positive pressure the ventilation of the lung takes place at a lowered level. During a narcosis in which respiration continues the lung-ventilation is diminished in the first three minutes by about 60 per cent. of its original value, and by a similar amount after prolonged anæsthesia. They consider that the carbon-dioxide content of the blood is reduced below a threshhold value by any state of hyper- pnœa prior to administration of the drug, and this diminu- tion in carbon-dioxide content *plus* the diminished excita-

bility of the respiratory centre would suffice to slow or abolish the activity of the centre. Gas analyses actually show that with a deep and rapid respiration there is a marked fall in the carbon-dioxide content of the blood. They also bring forward evidence to show that the diminution in oxygen content of the blood during chloroform narcosis is not due entirely to diminished alveolar ventilation, but to the action of the drug on the red corpuscles. —Lord **Berkeley** and M. P. **Appleby**: (1) The boiling point of water; and (2) the boiling points of some saturated aqueous solutions.—Dr. R. T. **Glazebrook**, W. R. **Bousfield**, and F. E. **Smith**: The heating effect of the currents in precise measurements of electrical resistance.

Linnean Society, November 2.—Dr. D. H. Scott, F.R.S. president, in the chair.—Dr. D. H. **Scott**: The Palæozoic fern *Zygopteris Grayi* (Williamson). The group of comparatively simple ferns (Primofilices of Arber, Cœnopteridæ of Seward) to which this plant belongs is chiefly known by petrified specimens showing structure. Correlation with impressions showing the habit has seldom been possible; fronds, however, belonging to a Zygopteris have been identified. *Z. Grayi*, a species founded by Williamson in 1888, is a rare fossil. A new specimen, from Shore Littleborough, in Lancashire, was found by Mr. Lomax last year, and series of transverse and longitudinal sections were prepared. The question whether this species belongs to Ankyropteris or Etapteris, as these genera are defined by Paul Bertrand, has been disputed. The new specimen is certainly an Ankyropteris, as shown by the presence of "peripheral loops" of small-celled xylem on the leaf-trace. Thus the view of Paul Bertrand is confirmed; it appears to hold good for all known specimens of *Z. Grayi*. *Zygopteris*, or, as we may now call it, *Ankyropteris Grayi*, is a highly developed member of the Primofilices, and presents interesting analogies with the curious genus Asterochlæna, recently described in full detail by Paul Bertrand. —Miss Edith E. **Bamford**: Pelagic actinian larvæ. The author stated that the collection of actinian larvæ from the Indian Ocean consists of thirteen different types, the chief interest lying in the four zoanthidean larvæ, all being new species of the genus Zoanthina, Van Beneden, represented by single specimens.—A. O. **Walker**: The distribution of *Elodea canadensis*, Michx., in the British Isles in 1909. *E. canadensis*, Michx., is said to have been first seen in Ireland in 1836 and in Berwickshire in 1845. By 1850 it had become so abundant in many parts of the British Isles as to be a serious nuisance by choking up canals, watercourses, and drains, and all attempts to clear it out failed. It was found, however, that after a few years it died out, or became comparatively scarce and feeble. Information on the subject is given in the paper from twenty-four counties in England and Wales, six in Scotland, and three in Ireland, showing, on the whole, that the plant has decreased of late.—Dr. J. **Murie**: The "slipper limpet" (*Crepidula fornicata*). It was pointed out that the "limpets" have now become a nuisance on the oyster-beds of both Kent and Essex. Originally they were imported from America, coming among the barrelled oysters brought over for relaying. They have since become thoroughly naturalised, and on the Blackwater and River Crouch are dredged up in tons attached to the oysters, mussels, &c. Unlike the starfish, devourers and arch-enemies of the oyster, or the mussels, which smother them, and the whelk tingles, which bore through their shells, the "slipper limpet" is more of a commensal parasite and messmate, partaking of the oyster's food. But what now chiefly renders them a serious menace to oyster-culture is the labour and expense involved in constant dredging for them, as likewise the necessity for individually chopping them off by "cultack" before the oysters are presentable for sale or replanting.

Zoological Society, November 7—Mr. Frederick Gillett, vice-president, in the chair.—T. E. **Gunn**: The presence of two ovaries in certain British birds, more especially the Falconidæ. The author outlined the views held by the majority of English morphologists on the reproductive organs of adult female birds, and enumerated examples which he had collected during a number of years where the right as well as the left ovary was present, and, so far as could be ascertained, in the two cases of which sections had been made, where the right ovary was functional. He pointed out the extraordinary preponderance in his examples of paired ovaries occurring in the Falconidæ, as compared with those derived from any other source, and remarked that in that family the ovaries were usually placed symmetrically one on either side of the vertebral column and at about the same level. In examples other than the Falconidæ this symmetrical arrangement was the exception rather than the rule, the right ovary generally occupying a position almost directly below the left, in the left half of the body-cavity, which, in the author's opinion, suggests a half-way home on the road leading to the final disappearance of the right ovary.—D. **Seth-Smith**: The moulting of the King penguin (*Aptenodytes pennanti*) in the society's Gardens. The author referred to Mr. de Winton's paper on the same subject which appeared in the Proceedings in 1898. The specimen observed by Mr. de Winton did not moult until it had lived sixteen months in the Gardens, whereas the specimen now in the menagerie had moulted twice in six months. The author stated that the new feathers were almost fully grown before the old ones were shed, and that the latter had to be rubbed off by the bird's beak or feet, as they were firmly attached to the sheaths of the new feathers. The paper was illustrated by photographs, which showed the bird in various stages of the moult, as well as by specimens of the shed feathers.—Prof. A. D. **Imms**: Some Collembola from India, Burma, and Ceylon, with a catalogue of the Oriental species of the order. Four genera and twenty-eight species were described as new, amongst the latter the most remarkable being a form unique among Collembola in possessing a median cercus to the fifth abdominal segment, and for the reception of which a new subfamily was formed. The total number of Collembola known from the Oriental region was stated to amount to fifty-three species comprised within twenty-seven genera.—Prof. P. P. **Sushkin**: Ontogenetical transformations of the bill in *Ardea cinerea*. The author gave a description of the gradual development of the bill in a series of embryos and young specimens of the heron upon which he had made observations. The simple rhamphotheca proved to be only a late stage of the compound one, and the form of the Ardeine bill he regarded as a derivative one, and discussed its resemblance to those of allied forms.

MANCHESTER.

Literary and Philosophical Society, October 31.—Prof. F. E. Weiss, president, in the chair.—Thomas **Thorp**: A new method for testing the curvature of parabolic mirrors. The method consists in tilting the mirror with a delicate tangent screw so that each portion of the mirror is successively brought into a horizontal position. —Miss P. C. **Esdaile**: A study of the scales of the salmon. It was shown that no two scales of the many scores examined from different parts of the one fish had the same number of lines, though they all had the same number of *annual* markings. Research during the past year indicated that the number of lines in each annual group increases gradually on scales taken from near the head to those taken near the fleshy (adipose) fin; and then from this position to the tail there is a decrease in the number of lines in each annual group. Also, the scales on the upper side of the body have fewer lines than those on the lower side. Thus the scales are not all of the same size, increasing in length and breadth as the number of lines increases. Near the adipose fin, the part of the fish with nearly the smallest girth, the scales are, so far as known, the longest and broadest, and have the greatest number of lines. The results clearly indicate that as yet it would be premature to state how many lines are formed during each year or each month.

November 14.—L. V. **Meadowcroft**: A geometrical treatment of geodesic torsion.—Dr. A. A. **Mumford**: Observations on some factors which have caused the improved physique of boys at the Manchester Grammar School during the last thirty years. In comparing the differences in height, weight, and physical development generally of the boys at the school during the period 1881–6 as compared with the period 1905–10, the author discussed the causes—better housing, improved diet, greater insight into the meaning of parental responsibility as regards health, &c.—to which he attributed the remarkable increase in height and weight of the boys. He referred to the changed attitude

towards athletics and physical culture, particularly during the earlier ages, prevailing to-day, and, further, directed attention to the fact that, from the statistics he put forward, it appeared that the later the onset of infectious diseases can be postponed beyond the earliest years of childhood, the better it would appear to be for the future growth and vigour of the child.

PARIS.

Academy of Sciences, November 13.—M. Armand Gautier in the chair.—J. **Violle**: A reversion of the double rose to the single form. A de Dijon rose, which for the last twelve years had borne large numbers of the usual double flower, possibly as a consequence of the dry and hot summer suddenly in September developed on all its branches single roses. These were followed eight days later by a crop of the usual double rose.—A. **Laveran** and D. **Roudsky**: Concerning the action of oxazine (triaminophenaxoxonium), chloride, and acridine (diphenylmethane) on trypanosomes. An account of experiments on the cause of the disappearance of the centrosomes from the trypanosome under the action of oxazine.—Pierre **Termier**: The tectonic in French Basque country.—J. Ph. **Lagrula** and H. **Chrétien**: The Brooks comet (1911*c*); its photographic appearance and its spectrum. The photograph showed a clearly defined globular nucleus with a tail formed of numerous filaments, nine of which were sufficiently well marked to measure their angles of position. The spectrum was photographed on a pinacyanol plate, recording from the ultra-violet to the red. It proved to be very similar to the spectrum of the Daniel comet taken with the same apparatus. The spectrum was continuous, with the cyanogen and carbon bands superposed.—A. **Demoulin**: The Ω surfaces.—L. **Schlesinger**: A differential system with fixed critical points.—G. **Kowalewski**: A property of the transformations of Volterra.—M. **Jouguet**: The acceleration of waves of shock in wires.—Jean **Becquerel**: The propagation of light in fluorescent bodies. Neither in the ruby nor the emerald does the state of fluorescence sensibly modify the velocity of propagation of the radiations of the same period as those emitted. Within the limits of accuracy of these experiments a fluorescence absorption does not appear to exist.—Kr. **Birkeland**: Celestial phenomena and experimental analogies. Photographs of further experiments made with a magnetic globe as kathode in a large Leyden jar. The examples given in the reproductions of the photographs include the imitations of Saturn's ring, of some nebulæ, and of the sun-spots.—Pierre **Weiss** and O. **Bloch**: The magnetisation of nickel, cobalt, and of alloys of nickel and cobalt. For those alloys for which magnetic saturation was possible, the Curie constant was found to be a linear function of the percentage composition of the alloys.—Chaspoul and Jaubert **de Beaujeu**: Researches on the radio-activity of the waters of Vals-les-Bains. No general relation appears to exist between the radio-activity of water and the mineral constituents. In the bicarbonate waters of Vals, however, the free carbonic acid varies in the same sense as the radio-activity.—Pierre **Girard** and Victor **Henri**: Concerning some new hypotheses on the molecular state of bodies in solution. The van 't Hoff-Arrhenius theory of solution has recently been criticised adversely by Colson and Fouard, the former on the basis of cryoscopic measurements, the latter from the results of osmometric experiments. The author shows reasons for supposing that in the experiments of Fouard the equilibrium observed was not that due to the true osmotic pressure, but was the result of osmotic currents of electrostatic origin. It is concluded that the facts brought forward by MM. Colson and Fouard cannot be regarded as controverting the theory of van 't Hoff and Arrhenius.—E. **Boismenu**: The hypoiodous amides. Details are given of the mode of preparation and properties of the iodine derivatives of acetamide, propionamide, and formamide. These all contain the group —NI, are decomposed by water, decolorise indigo, and liberate from a solution of potassium iodide twice the amount of iodine contained in the molecule. They are very unstable, and the stability decreases as the molecular weight is lower.—M. **Lespieau**: Some properties of monobromacrolein. Monobromacrolein gives pyrazol when treated with hydrazine hydrate; the aldehyde does not react with pure hydrocyanic acid, but a violent reaction is induced by the presence of a trace of potassium cyanide, the product being a nitrile alcohol giving the acid $CH_2:CBr.CH(OH).CO_2H$.—E. **Chablay**: Researches on the metallic alcoholates.—P. L. **Viguier**: Attempts at the direct preparation of tetrolic aldehyde. An account of unsuccessful attempts by three methods to prepare tetrolic aldehyde.—Marin **Molliard**: The action of various polyureides and of hippuric acid on the development and tuber formation of the radish. Tuber formation was found to be favoured by the presence of sodium urate.—C. **Picado**: The epiphyte Bromeliaceæ as a biological medium.—P. A. **Dangeard**: The sulphur bacteria.—M. **Radais** and A. **Sartory**: The toxic properties of the *Mapou* (*Agauria pyrifolia*). The leaves, flowers, fruit, and seeds of this plant contain a very toxic substance or substances soluble in water or weak alcohol. Boiling the solution does not destroy the toxicity. There are some indications that the toxic substance is a glucoside.—Paul **Godin**: Some conclusions from my researches on growth in man relating to puberty.—A. **Magnan**: A human acephalous monster.—Jacques **Pellegrin**: The aquatic vertebrates of the Sahara.—Louis **Semichon**: The heterogonic cycle of *Pterocallis tiliae* and the presence of chlorophyll.—D. **Keilin**: Certain constant sensitive organs in the larva of Diptera and their probable significance.—Henri **Agulhon**: The mechanism of the destruction of the diastases by light. Experiments with succase, laccase, and tyrosinase showed that these three diastases are not attacked by ordinary light in a vacuum. The ultra-violet rays from a quartz mercury vapour lamp partially destroys them, although not to so great an extent as when oxygen is present. The hypothesis that the actual agent destroying the diastases is hydrogen peroxide, formed by the action of the light, accords well with the experimental facts.—H. **Gaehlinger** and A. **Tilmant**: The caseifying action of certain lipoids.—Maurice **Lugeon**: Some consequences of the hypothesis of a dualism of the Palæozoic foldings in the western Alps.—G. **Le Cadet**: The origin of the electrical manifestations of storms, on the occasion of the observation of cyclones in China seas. In the vertical terrestrial electric field a vortex with horizontal axis can develop influence charges and sufficient differences of potential to cause disruptive discharges.—J. **Vallot**: The protection of observatories at high altitudes against lightning. In the two observatories on Mt. Blanc, one is surrounded by metal directly connected with the rock on which it stands by numerous metallic connections, and this has never been struck by lightning. The other, the Janssen Observatory, stands on snow, and connection has to be made with the earth by means of a cable 100 metres long. In spite of numerous alterations and additions to the protecting apparatus, this observatory has been repeatedly struck, and electrical phenomena have been observed inside the building, in some cases lasting for more than two hours, and resulting in personal injury to the occupants and fusion of various metal instruments and utensils. It is concluded that for buildings established on snow at a considerable distance from rock there is no means known of protecting against lightning.—M. de Montessus **de Ballore**: The distribution of seismic instability in Bolivia.

FRIDAY, DECEMBER 1.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Brake-lining Coefficients of Friction: J. and W. Legg.

CONTENTS.

THURSDAY, NOVEMBER 30, 1911.

THE SCIENTIFIC STUDY OF MAMMALS.

The Age of Mammals in Europe, Asia, and North America. By Prof. Henry Fairfield Osborn. Pp. xvii+635, with illustrations. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 18*s*. 6*d*. net.

DURING recent years no branch of study has made more important contributions to biology than that of extinct mammals. It has not only led to a more satisfactory understanding of the mammals themselves and their relationships. It has also thrown unexpected light on the general processes of organic evolution and the problems of geographical distribution. The broad features in the secular development of several groups of mammals are now better known than the growth stages in the individual life-history of many common existing species; and the underlying principles are often discoverable from a consideration of the numerous recurring phenomena which are sufficiently well known for comparison.

The literature of the subject, however, has become so voluminous and scattered that the time has arrived for an exhaustive critical summary. The aimless casual descriptions of so-called new species and varieties can only be superseded by real contributions to science when the present position of the various problems is clearly understood. Zoologists, especially palæontologists, are therefore much indebted to Prof. H. F. Osborn for the great labour he has bestowed on his new work, "The Age of Mammals," which furnishes the necessary summary by a master-hand and forms a sure basis for future research.

Prof. Osborn's volume is intended for general scientific readers as well as for specialists. It is thus prefaced by an interesting introductory section on the principles of palæontology as illustrated by extinct mammals, and on certain related geological questions. The treatment is more or less historical, with full references to the original authors, and there are several explanatory diagrams and maps. A table of strata (Fig. 13) marking the periods of successive earth-disturbances which gave rise to various mountain-systems, is especially striking. During the "Age of Mammals," or Tertiary period, the Pyrenees, Swiss Alps, and Himalayas have been formed in the Old World, while the Rocky Mountains have originated in North America.

It is well known that mammals first arose during the Secondary period, or "Age of Reptiles," but remained insignificant and restricted in their range until practically all the dominant reptiles had passed away. Prof. Osborn alludes more than once to this apparently sudden world-wide extinction of the dinosaurs, ichthyosaurs, plesiosaurs, and pterodactyls which flourished until the end of Cretaceous times; but it is only to emphasise the inexplicable nature of the phenomenon. As he remarks,

"Reptiles are so sensitive to temperature that it is natural to attribute this extinction to a general refrigeration, but the flora shows no evidence of this either in Europe or America; nor is there evidence of any great geographic cataclysm on the surface of the earth, for the plant-life transition from one age to the other in the Rocky Mountain region is altogether gradual and gentle."

Whatever may have been the cause, so soon as the great reptiles had disappeared, small primitive mammals of the kind which arose in the Secondary period suddenly began to multiply, and spread both in Europe and North America, perhaps also in South America. Their remains are found in the Basal Eocene deposits. None of these animals, however, appear to be directly ancestral to more modern groups, the direct forerunners of which arrived both in Europe and North America from some undetermined region in the period of the Lower Eocene. This second mysterious migration furnished the source of the lemurs, insectivores, true carnivores, rodents, and perissodactyl and artiodactyl ungulates. A few of the primitive mammals still survived with them through the Eocene until the beginning of Oligocene times, most of them grown unwieldy in size, such as the herbivorous Coryphodon and Uintatherium, or the carnivorous Mesonyx; but their brain remained small and simple, and they could not compete with the higher mammals in which advance in brain-power accompanied progressive elaborations in the limbs and dentition.

During the Oligocene period, sabre-toothed cats, dogs, martens, pigs, and rhinoceroses became recognisable, both in Europe and North America, while the viverrines occurred in Europe, and the hares and primitive camels were characteristic of North America. Africa was then a separate land-area, the scene of the early development of hyracoids and proboscideans. In all regions there were certain precocious and aberrant types, such as the titanotheres of North America and Arsinoitherium in Egypt, which only flourished for a short time, without leaving descendants. At the beginning of the Miocene period the most noteworthy event was the connection of Africa with Europe, which allowed the proboscideans to spread over the whole of the northern hemisphere, where they flourished and increased in size. There were now true cats and bears, tapirs, and rhinoceroses, both in the Old and New Worlds; while by the end of the Miocene the horses had nearly become one-toed, and apes, antelopes, okapis, and horned deer had appeared, at least in the Old World.

By the end of the Pliocene period mammals had become much as they are now, though most of the groups were more widely distributed, and they comprised many large species which soon disappeared after the advent of man. From the early Eocene until the early Pliocene, South America had been an isolated land-area, on which mammals had developed into several strange groups of ungulates and the true edentates (sloths, armadillos, and ant-eaters). Before the end of the Pliocene, the emergence of the isthmus of Panama permitted some of these types to wander north into the southern United States, while the camels (llamas and alpacas), cats, dogs, deer, pigs, horses, and mastodons were able for the first time to spread to the southern continent. At the end of the Pliocene period

there is evidence of extensive desiccation in western North America, southern South America, north-central Africa, and central Australia; and physical changes which are not yet understood led to a glacial epoch in the northern hemisphere in Pleistocene times. These phenomena had doubtless much to do with the extinction of the large quadrupeds and the impoverishment of the mammal fauna. Civilised man has continued the destruction.

The whole of this fascinating story is told in detail by Prof. Osborn, who not only discusses the mammals themselves, but also describes the rocks in which their remains occur, and briefly notices the successive changes in geography which they indicate. His work is illustrated by numerous text-figures of skeletons, restored sketches of extinct mammals made by the American Museum of Natural History, photographs of scenery, and diagrammatic geological sections. As might be supposed, much of it is extremely technical, and to be used for reference rather than systematic reading; but it is enlivened throughout by a succession of interesting generalisations, which are all the more valuable as having been either suggested or confirmed by the author's own researches. The peculiar feature of Prof. Osborn's book, indeed, is its stimulating freshness, and he is to be congratulated on the impulse which it is certain to give to the studies with which it deals. A. S. W.

GEOGRAPHICAL DISTRIBUTION OF FERNS.

Die Geographie der Farne. By H. Christ (Basel) Pp. 357+3 maps. (Jena: Gustav Fischer, 1910.) Price 12 marks.

DR. CHRIST has produced a volume of remarkable interest on the geographical distribution of ferns, which forms a worthy companion to Schimper's well-known "Pflanzen-Geographie auf physiologischen Grundlage." The book has been arranged in a somewhat similar manner to Schimper's "Plant Geography," and is divided into two parts. The first consists of 136 pages, devoted to considerations of the effects of soil, climate, &c., on the distribution of ferns, and in the second part the ferns of the different geographical areas are described in detail.

To the general botanist, and more particularly to the ecologist, the first portion of the book has the greater interest. Ferns, unlike the flowering plants, though very widely distributed, are not universally found over the surface of the earth, since they are definitely limited as to their environment by the need for water, and though many species are remarkable for their capability of resisting desiccation, yet they are unable to grow where the rainfall is below a certain amount. Being in the main shade plants, their maximum distribution tends to follow the wooded areas of the globe; and the dry desert areas are almost destitute of ferns.

Though mainly found growing on humus, some ferns are affected by the nature of the substratum, and this is especially the case with calcareous soils. It may often happen, however, that chalk-shunning ferns may be found on that formation owing to the depth of humus by which the calcareous soil is overlaid.

Striking examples of ferns which avoid the chalk are afforded by *Asplenium septentrionale* and by the world-wide *Pteridium aquilinum*—the bracken fern—which is found in both hemispheres, from "the equator to the poles." *Asplenium viride* and *Cystopteris montana*, on the other hand, may be cited as examples of species characteristic of the chalk. Halophytes, again, have their fern representatives, and *Acrostichum lomarioides* from the brackish swamps of tropical America, and *A. aureum*, which grows in the Rhizophora estuaries, are striking examples of this type of plant.

Then again there are the fresh-water swamp ferns, such as the widely distributed *Dryopteris thelypteris* and the well-known water fern, *Ceratopteris thalictrioides*.

The majority of ferns are perennial, but there are a few exceptions, of which Ceratopteris is one, and also the annual fern, *Anogramma leptophylla*.

Ferns afford parallels to Phanerogams in their choice of habitats and relations to climatic conditions, and also in their external forms they provide counterparts to other types of vegetation. We find them, for example, as epiphytes; tree ferns; scramblers or bramble ferns (Gleichenia, Odontosoria, &c.); twining ferns, such as *Blechnum volubile;* tendril climbers (*Lathyropteris madagascariensis*), and creeping epiphytes or rhizome climbers, which are well illustrated by the aroid-like *Oleandra neeriformis*.

The general biological features of hygrophytic ferns, hairs, secretions, storage organs, &c., are also described with a wealth of illustration.

An interesting section is devoted to the description of the xerophytic types, many of which have their home in the Andes, on the same lines as that for the hygrophytes. Two characteristic forms may be recognised: the Cheilanthes type, with short rhizome, deep roots, and small hairy pinnæ, and the Elaphoglossum type, where the rhizome is thick and creeping and the leaves tongue-like, leathery, and simple. The genera Cyclophorus, from the Old World, and Elaphoglossum, centred in the Andes, afford the most striking examples.

Ferns of high alpine or arctic regions are few, and, as compared with the phanerogamic vegetation of such situations, are not particularly characteristic. Cryptogramma and Woodsia, however, may be cited as typically northern alpine forms, while *Polystichum mohrioides* is a typical antarctic-andine species. One of the highest known species is another Polystichum, *P. Duthei*, from Kumaon, which occurs at an altitude of from 13,000 to 17,000 feet.

The bulk of the second part of the book is concerned with the fern flora of the different geographical regions, but it is preceded by some very interesting pages dealing with general questions of geographical distribution, such as the effect of the Ice age and the relics of the fern flora of past ages. The distribution of several genera is outlined, but space does not permit of a review of this section of the book in further detail. Attention may, however, be directed to the remarkable case of distribution afforded by

the genus Pleurosorus, which is found as three scarcely differing forms in Southern Spain (*P. Pozoi*), South Chile (*S. papaverifolius*), and Australia (*P. rutaefolius*). These small xerophytic rock ferns may well be cited as examples of the simultaneous appearance of a species in widely separated localities.

There is but one fault to find with this otherwise excellent book, and that is that the illustrations, most of which are very good, have been inserted without any particular reference to the text, and some difficulty is experienced in attempting to find the figures which are intended to illustrate particular descriptions.

A. W. H.

OPHTHALMIC THERAPEUTICS.

An International System of Ophthalmic Practice. Edited by Dr. Walter L. Pyle. Therapeutics. By Dr. A. Darier. Translated by S. Stephenson. Pp. xiv+444. (London: Rebman, Ltd., 1911.) Price 17*s.* 6*d.* net.

THIS is the first volume of an "International System of Ophthalmic Practice," edited by Dr. Walter L. Pyle, of Philadelphia. Other volumes announced are on "Medical Ophthalmology," by Dr. Arnold Knapp, of New York; "Ophthalmic Diagnosis," by Dr. Charles H. Beard, of Chicago; "Pathology and Bacteriology of the Eye," by Messrs. Treacher Collins and M. S. Mayou, of London; "Affections of the Orbit and Accessory Cavities," by Dr. Christian R. Holmes, of Cincinnati; "Examination and Refraction of the Eye and Eye-strain," by the editor; and "Ophthalmic Surgery," the authorship of which is not stated. It will be seen that the scheme is comprehensive, and that the aim is essentially practical. The authors are men of established reputation, and may be relied upon to carry out their work ably, so that the system will form a valuable, if not indispensable, addition to the ophthalmologist's library. If the volumes reach the standard of the sample which we have before us we may confidently prophesy the financial success of the series.

Those who have read Dr. Darier's lectures and papers on ophthalmic therapeutics in their original form in French must have approached the present work with some misgivings. Dr. Darier is an enthusiast for *novae res*. He possesses in marked degree the mental agility of the Latin race, quick to appreciate new facts, eager to traverse new paths. True, he sometimes appears to the onlookers to skip rather than to run, but then he is an artist, and a savour of art is not without its uses in dealing with the science of medicine, a science which, though yet in its infancy, is called upon to perform the feats of mature development. Dr. Darier's enthusiasm often outruns discretion, but in this book it has been curbed by the "free editorial control" which has been exercised upon the manuscript. In the end we have a sound work on the treatment of diseases of the eye, which by virtue of the large space devoted to the discussion of new methods and new drugs, forms a useful adjunct to the formal text-book.

The subject is divided into two parts, general and special therapeutics. The first commences with a chapter on methods of diagnosis, devoted to such topics as serum diagnosis and the demonstration of spirochætes. Constitutional treatment is then dealt with, stress being laid upon the technique of hypodermic and intravenous medication and subconjunctival injections. The chapter on serum- and organotherapy will prove particularly useful to the ophthalmologist, who has perforce to obtain his knowledge of these matters second-hand. It might have been expanded with advantage, and a freer citation of original papers would have enhanced its value. The ophthalmologist cannot afford to ignore serum-therapy, which now has so large a place in medical treatment, but it is a two-edged weapon, and should be used with the utmost caution. Much space is devoted to photo-electro-, hydro-, mechano-therapy, X-rays, and radium; as a rule original papers are quoted, and the reader is left to draw his own conclusions. Of more value are the chapters on drugs—anæsthetics, analgesics, vaso-dilators, vaso-constrictors, mydriatics and cycloplegics, miotics and silver compounds; their virtues and vices and the modes of their application are quite well described.

In the section on special therapeutics, the diseases of the eye are dealt with seriatim in the manner of an ordinary text-book. Too little stress is laid upon old and well-tried methods, so that the reader is liable to obtain a wrong perspective. The book, however, is clearly intended for specialists who are capable of forming an independent opinion in these matters. It would be easy to criticise many of the statements, but those most open to attack are such as only time and extended experience can ultimately settle. They are topics of constant dispute in ophthalmic journals, where they can most suitably be ventilated. In discussing cataract, glaucoma, and so on reference has to be made to operative measures. It would have been better to have relegated these matters entirely to the volume on ophthalmic surgery, where they will doubtless be treated exhaustively. The cursory remarks are of little value; on the other hand, they do not occupy much space.

We can cordially recommend the book to the consideration of advanced students of ophthalmology, and they will be well advised to look out for the other volumes of the series.

PHARMACOGNOSY IN THE UNITED STATES.

A Text-book of Botany and Pharmacognosy, intended for the Use of Students of Pharmacy, as a Reference Book for Pharmacists, and as a Handbook for Food and Drug Analysts. By Prof. H. Kraemer. Fourth revised and enlarged edition. Pp. viii+888. (Philadelphia and London: J. B. Lippincott Co., n.d.) Price 15*s.* net.

ALTHOUGH in English text-books botany is not usually combined with pharmacognosy, it is undeniable that such a combination possesses for the student of the latter science the distinct advantage that much overlapping may be avoided, and that, by selecting medicinal plants to illustrate the botanical portion, the student, while studying botany, insensibly acquires a considerable amount of information con-

cerning economically important plants. This advantage has been utilised by Prof. Kraemer to the fullest extent; indeed, it might be considered by some to have been carried rather too far, for the section on the "Classification of Angiosperms" deals with medicinal plants only. The botanical portion of the work is well written and abundantly illustrated; it is characterised by the comparatively small amount of attention given to the lower forms of vegetable life, the algæ and fungi occupying only thirty-six pages, whereas in text-books of botany these two groups are usually treated in detail that is often considered unnecessary for the pharmacognosist.

Part ii., "Pharmacognosy," is subdivided into four chapters, dealing respectively with crude drugs, powdered drugs, reagents, and micro-analysis. As the first chapter comprises only 178 pages, and deals with a large number of crude drugs, it is evident that the space allotted to each can be but small. The descriptions of the drugs are accordingly very concise, and the methods by which those that are unorganised are produced have been perhaps unduly reduced, but the constituents have received careful and sufficient treatment. Thus the accounts of the production of such important drugs as aloes, catechu, guaiacum, rubber, &c., can convey to the mind of the student but an imperfect idea of the various steps in the processes and their effect upon the drug obtained. To these details a little more space might well be given without unduly increasing the size of the work. Credit, however, must be given to the author for including a large number of drugs of comparatively rare occurrence, and thus making this section of the work more complete than is usually the case with text-books designed for the use of the student. Chapter ii., dealing with powdered drugs, has also been much elaborated. In addition to those with organised structure, it includes a number of structureless drugs (aloes, myrrh, &c.), as well as a few definite chemical compounds. The key to their identification, based primarily upon the colour, is one of the most complete that has been published. The chapter is abundantly illustrated, and contains descriptions of the microscopical characters of so many drugs that it cannot fail to be of service to the experienced microscopist as well as to the student.

Chapter iv., "Micro-analysis," deals with the identification of the crystals found in drugs and their preparations by crystallographic methods, and the time has arrived when these methods must be adopted in the study of such crystals if any real progress in that direction is to be made. It is undeniable that at present the crystals observed in drugs are often very loosely described, and that their identification frequently rests on very insufficient grounds. This part also includes the description and illustration of the crystalline forms of a number of active constituents of drugs, such as brucine sulphate, codeine sulphate, cubebin, &c., and is to be regarded as suggestive (which is certainly the case) rather than as complete.

It will thus be seen that Kraemer's text-book is a valuable contribution to the literature of pharmacognosy. It shows how medicinal plants may be utilised in the study of botany; it deals with a large number of drugs; it gives instruction in their identification in the powdered state, and it suggests lines upon which microscopical investigation may be prosecuted. The author is to be congratulated on the success of his labours. HENRY G. GREENISH.

THE CHEMISTRY OF BLEACHING.

The Principles of Bleaching and Finishing of Cotton. By S. R. Trotman and E. L. Thorp. Pp. xii+347. (London: C. Griffin and Co., Ltd., 1911.) Price 16*s*. net.

THE book before us is an attempt to blend an account of the most recent advances in the processes of bleaching and finishing of cotton goods with an equally up-to-date account of the scientific principles which form the basis of these processes. Such an attempt is comparatively rare in connection with manufacturing processes, and on that account alone the book ought to be welcomed. But when, as we find, the attempt has been highly successful, the authors must be congratulated on having produced a work of great value to all concerned in this important industry.

The book opens with an account of the structure and composition of cotton fibre, the means of testing its strength, twist, &c., followed by an account of the carbohydrates, such as starch and the sugars which are of importance to the bleacher. A full account is given of the different kinds of water, and of the means of treating it so as to make it suitable for bleaching purposes. The importance of the quality of water supplied to the works is too often overlooked by the bleacher, who ought to know that good results in bleaching largely depend on the quality of water used, and that the pure white required for some goods cannot be obtained if certain waters are used.

One of the most interesting chapters in the book is that in which the influence of bacteria in bleaching is discussed. The authors show that cotton may be infected with bacteria at almost every stage of its manufacture, and the principal causes are the following:—

(1) Impure water for steeping.

(2) Incomplete removal of protoplasmic constituents during bleaching.

(3) Allowing goods to lie about in a damp condition, especially in warm weather.

(4) Insufficient cleanliness of plant or buildings.

(5) The use of inferior materials, *e.g.* low-grade starches and glues.

(6) The careless storing of finished goods.

The results of bacterial damage are frequently coloured spots, each spot being a colony of the organism. Sometimes the whole piece of cloth becomes infected, and has the appearance of having been dyed. A piece of lace examined by the authors left the finisher apparently perfect, but subsequently developed a pink colour.

"A microscopic examination showed the presence of numerous very fine hyphæ interlaced with the cotton fibres, and subsequent plate cultures upon a starch medium similar to the dress used for the lace proved the presence of a chromogenic mould, which was

capable of producing the observed pink colour. The point was conclusively proved by infecting sound lace with the organisms."

Further, it was found that the presence of acid was necessary to develop the colour, which only appeared after about fourteen days. This explained how the goods were passed as perfect by the finishers. Naturally much space is devoted to the treatment of the cloth before the actual bleaching and to the materials and plant used in these processes. The importance of securing purity in the materials used is insisted on, and regular testing recommended. Full details are given of the Kiers used for lye boiling and washing, and there are excellent illustrations of the most improved forms of plant.

Much attention is given to the various bleaching agents, and particularly to bleaching powder. The controversy as to its composition is carefully considered, but cannot yet be said to be finally settled. Reference is made to the very recent work of R. L. Taylor (Chemical Society's Journal, 1910, p. 2541), who has shown that the action of carbon dioxide on bleaching powder liberates chlorine only and not hypochlorous acid, as had usually been supposed. On the other hand, S. H. Higgins maintains that hypochlorous acid does enter into the bleaching action (Chemical Society's Journal, 1911, p. 858).

Limitations of space will not allow us to refer to other portions of the book. Suffice it to say that the use of other bleaching agents, such as sodium hypochlorite ozone, sodium peroxide, potassium permanganate, &c., is referred to, and there is a full account of the bleaching by electrolytic solutions, and a discussion of the economy of the process. The book will be of special use to bleachers who have a sufficient knowledge of chemistry to understand the theoretical portions.

SYSTEMATIC PSYCHOLOGY.

A First Book in Psychology. By Prof. Mary Whiton Calkins. Pp. xvi+419. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 8*s*. net.

Erkenntnistheorie. Von Prof. E. Dürr. Pp. viii+362. (Leipzig: Quelle und Meyer, 1910.) Price 8 marks.

MISS CALKINS is well known among psychologists for her treatment of psychology as the science of selves rather than as the science of mental processes. In her view, the science is best treated as "a study of conscious selves in relation to other selves and to external objects—in a word, to their environment, personal and impersonal." The aim of the present book is to give a systematic account of the various psychological topics, ordinarily treated in introductory text-books, from this point of view. As might be anticipated, Miss Calkins is least successful in her method when dealing with perception, imagination, memory, and thought, although the special point of view gives an added significance to the facts, and brings a new interest for those students who have already become familiar with the ordinary descriptions. When dealing with the more individualising and active forms of consciousness—emotion, will, belief, and the religious consciousness—the author is able to benefit by her method to the full, and gives the impression of concreteness and reality so often missing in the descriptions of these aspects of conscious life. There is no chapter specially devoted to the nature of the self, but many facts generally given under this head are very fully discussed in a section on "Abnormal Psychology" in the appendix. This appendix forms quite a third of the entire volume, and contains masses of detail the enumeration and discussion of which might obscure the general line of argument. It adds very greatly to the value of the book, and is clearly arranged, and well provided with figures and diagrams. The final section contains a large number of good "review questions."

Prof. Dürr's book, though written from the psychological point of view, does at least equal justice to the metaphysical issues involved in the problem of knowledge. It is divided into three long chapters entitled, "Die Psychologie des Erkennens," "Die Wertlehre des Erkennens," and "Die Gegendstandslehre des Erkennens" respectively, and under each of these headings numerous subdivisions occur. The book cannot be accused of lack of system, and in some respects forms a compendium of philosophy with the historical and critical methods about equally represented. Its first hundred pages on the psychology of thought, however, lift it far above the ruck of ordinary philosophical text-books, and make it of the greatest value to the psychologist. The difficulties attending the various possible theories of outer perception and inner perception (introspection) are exhaustively discussed, though in small compass, and the peculiar psychological problem involved in the case of memory and recognition is clearly stated, and a solution of it attempted. Under the sub-heading "Thought," theories of abstraction, judgment, inference, and induction are briefly considered. Several paragraphs are devoted to the question of the relation of knowledge to belief. Notes at the end of the volume give the necessary references to current literature, and in many cases continue the discussion in greater detail. The one criticism to which the book is open is that difficulties are treated in too summary and dogmatic a fashion. For conversational classes or "seminars" in philosophy and general psychology, the book should prove invaluable. There is certainly no single book in English of a similar kind at the present time.

W. B.

OUR BOOK SHELF.

(1) *Introduction to Science.* By Prof. J. Arthur Thomson. Pp. vi+256.

(2) *Astronomy.* By Arthur R. Hinks. Pp. vi+256. (Home University Library of Modern Knowledge.) (London: Williams and Norgate, 1911.) Price 1*s*. net each.

(1) PROF. THOMSON has prepared an admirable introduction to the scientific section of the series of which he is joint-editor. He has an inspiring gospel to expound, and has proved himself a worthy apostle of it. Science stands for truth and righteousness, for exact observation, for progress at all costs, for that divine discontent with existing knowledge which stimulates persistent inquiry into the unknown, and

leads the true philosopher, in Sir John Herschel's words, "to hope all things not impossible and to believe all things not unreasonable."

The scientific mood, aim, and method are described by Prof. Thomson and illustrated by apt quotation from the works of active investigators. The relations of science to philosophy, art, religion, and practical life are dealt with; and the classification of the sciences forms the subject of a particularly valuable chapter. As is appropriate in a "Home University Library," the readers are assumed to come to the university with a certain foundation of preliminary knowledge; otherwise such a reference as that to "Bode's law of the relations of the planets, or Mendeléeff's 'periodic law' of the relations of the atomic weights of the chemical elements" would be unintelligible. Given this acquaintance with the broad principles of science, we can conceive no better first survey of the significance of scientific work than that which Prof. Thomson provides.

(2) Mr. Hinks has produced a volume which is decidedly superior to most popular books on astronomy, inasmuch as it is not merely a descriptive catalogue of the characteristics of celestial bodies, but a statement of leading results and a critical analysis of conclusions. The book breathes the spirit of the practical astronomer who can form his own opinion as to the value of observations and hypotheses. It suffers by comparison with some other volumes on account of the absence of illustrations; nevertheless, it is decidedly original in substance, and the most readable and informative little book on modern astronomy we have seen for a long time.

Physikalische Chemie der Zelle und der Gewebe. By Prof. Rudolf Höber. Dritte Auflage. Pp. xv+671. (Leipzig: W. Engelmann, 1911.) Price 17.25 marks.

THIS third edition of Dr. Höber's well-known work on the physical chemistry of the cell and tissues is widely different, both in extent and quality, from the modest little volume which first appeared in 1902, and interested physiological chemists as the evangel of the new lipoid theory of cell permeability promulgated by Overton and Hans Meyer.

Since that time the chemistry of colloids and of the relationships of colloids and crystalloids has made enormous strides, and the new edition is now in reality an interesting and fairly well up-to-date text-book of this domain of knowledge. It still shows, however, on account of the way the lipoid theory keeps cropping up everywhere, manifest traces of its origin, and the author is still an earnest and whole-hearted believer in an ingenious theory which has not stood the test of advance of time and growth of knowledge.

Even this sturdiest champion of the lipoid theory is driven now to admit that the experimental findings can only be explained by following Nathansohn's postulations of a mosaic cell-membrane, in which the small stones represent the lipoids and the interstitial material, a protoplasmic cement which allows a varying degree of permeability to the ions. This is accordingly a kind of dual Maxwell's demon membrane, with one kind of demon at one kind of gate letting through the lipoid-soluble bodies, and a different class of demon at a different sort of gate letting through the water-soluble bodies, and those who desire salvation for the lipoid-theory by leaving it in possession of these two demons may be congratulated on having placed it where it is well-nigh unassailable, unless, indeed, someone discovers a substance which is soluble neither in water nor lipoids and yet can contrive to get into cells.

The portions of the book which do not treat of cell permeability are well and clearly written, and give a full presentation of the subject, which may be recommended for study to those interested in the confines of physical and bio-chemistry who possess already some acquaintance with both subjects. It is not by any means a book for beginners.

BENJAMIN MOORE.

Geologische Ausflüge in der Mark Brandenburg. By K. Hucke. Pp. 155. (Leipzig: Quelle und Meyer, 1911.) Price 3.20 marks.

THIS guide for the geological student and tourist, printed in the popular black-letter type of northern Germany, should find a ready appreciation among those who travel round Berlin. The descriptions of the various excursions are clear, and there is a touch of Walther's vividness here and there, as in the account (p. 13) of the general landscape on the withdrawal of the "inland ice." Not enough is made, perhaps, of the probability that large areas of this ice stagnated in the plain, and that the withdrawal, which deposited the ground-moraine, was mainly in a vertical direction.

The index does not always guide us to the attractive generalisations which the book contains, such as the origin of the numerous lakelets and the ancient courses of the streams (p. 107). When the visitor, however, reaches a critical district he is encouraged to look beyond the immediate landscape. Formations concealed at the surface are sought in quarries underground. An interesting account is given (p. 121) of the interglacial bed of red ochre near Dahnsdorf, resulting from the oxidation of dark green iron carbonates and humates. These were deposited by water, and were subsequently preserved by boulder-clay, as a stratum 30 metres thick. The dry channels known as Rummeln (p. 136) in the elevated region of the Fläming south of Berlin are attributed to torrents from the melting ice. A new interest is thus given to these pleasant features of a land that often seems monotonous. We are told that the horizontal sheep-tracks along their sides (Fig. 55) have been regarded as river-terraces.

In the gloom of the level forest-covered regions the huge Scandinavian erratics form features of themselves (Fig. 32). The numerous photographs that illustrate this handy volume are mostly provided by the author, who has certainly shown the wide variety of deposits that may be studied in the Mark of Brandenburg.

G. A. J. C.

Playbooks of Science: Chemistry and Chemical Magic. Pp. 150. *Mechanics and Some of its Mysteries.* Pp. 120. *Flying and Some of its Mysteries.* Pp. 138. All by V. E. Johnson. (London: Henry Frowde, Hodder and Stoughton, 1912.) Price 1s. 6d. each.

BOYS who are thoroughly interested in a well-chosen hobby are the cause of much less anxiety to their parents and teachers than those who are content to idle away leisure hours. The author of these little books has for his primary aim the provision of intelligent amusement, and on the whole he has made a successful appeal to the desire young people have "to try things." "Never be content merely to read about an experiment" is the advice offered at the beginning of each book, and it is probable that many boys will be led from the performance of the tricks described to the serious study of the phenomena observed.

The two books named first are almost wholly devoted to experiments, while the third is largely a descriptive account of the various attempts to evolve the perfect flying-machine.

Der Panamakanal. By Max D. Fiegel. Pp. viii+183. (Berlin: Dietrich Reimer—Ernst Vohsen, 1911.) Price 4 marks.

Mr. Fiegel describes clearly the course of the canal now in process of construction by the United States Government; also the engineering works and machinery, and the commercial and political aspects of the enterprise. His book will provide German readers with an informative account of the position about a year ago of what in three years' time promises to be one of the most remarkable human schemes ever brought to a successful conclusion.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Weather of 1911.

Sir Edward Fry's letter in Nature of November 16, and Commander Hepworth's reply in the issue of November 23, prompt me to give expression to some ideas which I have been discussing with various meteorological friends during the last few months. What I have to say will not attempt an explanation of the phenomena of the remarkable summer and autumn of this year, but it will give an indication of the direction in which, for my part, I hope to look for an explanation of those phenomena.

I agree with Sir Edward Fry that the prevalence of anticyclones in a particular direction, or the continuance of given winds, are only part of the phenomena to be explained; I think, too, that the statement may be rightly understood in a sense slightly different from that which Sir Edward intended. I mean that this summer furnished a good deal of evidence for a proposition which includes the inference that the distribution of pressure is not in itself a complete explanation of the weather. I will state my proposition now, and afterwards explain why I make it. It is that the main outlines of the distribution of pressure are imposed upon the surface layers of the atmosphere by transmission from a region 9 or 10 kilometres high—a region which is above what may be called the physical laboratory, where rain and thick clouds are made—and that the phenomena of weather are due, not to the mere existence of the air currents which correspond with the distribution of surface pressure, but to their heterogeneity. Weather as represented primarily by rainfall is dependent on the convection of moist air, while pressure distribution is governed by changes which take place above or nearly at the top of the convective region of the atmosphere. In other words, the dynamics of the atmosphere is controlled in the upper air, while the physics of the atmosphere is a matter which concerns the lower layers.

The remarkable summer has provided evidence in support of this proposition by furnishing a number of examples of pressure distributions which might well have been rainy, and were not. The Coronation festivities were somehow preserved from the copious rainfall which, according to the pressure distribution, was their due. If pressure distribution is the cause of rainfall, 100,000 children at the Crystal Palace on June 30 ought to have got wet through, but they did not. There are many other instances of the same kind which I need not quote. Let us look at the matter from the other side.

Some time during the summer Mr. W. H. Dines sent to me the results of some work which he has done upon the correlation of various data for the upper air. Among them was the correlation coefficient between the variations of pressure at the surface and at the level of 9 kilometres. For certain groups of ascents it was so large as to show a close approximation to proportionality. That is, of course, not surprising, because the variations at the surface and at 9 kilometres are certainly not independent; but what was surprising to me was that the standard deviations of pressure at the two levels in the cases under investigation were very nearly equal. Thence it follows that the pressure variations at 9 kilometres level (with two-thirds of the atmosphere below it) are not merely proportional to the variations at the surface, but the same in magnitude; and as they are certainly transmitted to the surface, it follows, further, that the variations at the surface are practically accounted for by the variations that occur at 9 kilometres. We are accustomed to urge the importance of the study of the upper air for increasing our knowledge of meteorology; but, so far as I know, we have not recognised that it was so directly responsible for steering our surface air currents.

Mr. Dines's variations were those shown between the individual balloon ascents and their average. Looking into a series of charts for the upper air recently published by Prof. Rotch, I came upon another step in the proof. In the charts Prof. Rotch gives the average wind velocity at 30,000 feet (9 kilometres) and the atmospheric density there. The product of these two is about the same as for a point near the surface, whence it follows that for Blue Hill the pressure gradient at 9 kilometres, which is proportional to the product, is the same as for the surface; in other words, not only are the chronological changes transmitted to the surface from 9 kilometres, but the average pressure distributions are similarly transmitted. In a discussion at the Meteorological Office on October 23 I was reminded that these conclusions are not new. The inverse proportionality of velocity and density of air is known as Egnell's law; and the approximate constancy of pressure gradients up to 9 kilometres was pointed out to the British Association by Gold and Harwood in 1909. But the idea of looking to the level of 9 kilometres for the outlines in full scale of our surface distribution of pressure is new; and it seems to me to be possibly the beginning of a new era in the endeavour to explain such phenomena as those of the past summer.

I cannot, at this stage, give particulars as to the details of the application of so general a proposition to special cases, such as circular revolving storms, the northern sides of which may be confined to the lower strata, nor can I say whether the application of the proposition is limited to certain parts of the world. I think it must be. It will be remembered that M. Teisserenc de Bort computed mean isobars at 4 kilometres for January and July that showed the average circulation of the upper air in each hemisphere as a great cyclonic depression, with centres at the poles. It is not likely that there is any great change of distribution between 4 kilometres and 9 kilometres. At Blue Hill the winds at 3 kilometres vary between W.S.W. and N.N.W., and these, again, should agree with the pressure distribution. We know from the study of the points where sounding balloons land that the westerly circulation is not always to be found aloft. We know, also, that at 9 kilometres the variations of temperature from day to day are as large as, or larger than, those at the surface. Hence we may conclude that the pressure distribution at 9 kilometres corresponds with a cyclonic circulation of westerly winds round the pole, periodically, but perhaps not regularly, invaded by winds from some northerly quarter, with marked changes of temperature. This will be recognised as merely a rough description of a series of **V**-shaped depressions, which also, on the average of the month, would give a westerly circulation. Possibly, in reality, the **V**-shaped depressions at 9 kilometres are made up of comparatively warm westerly winds with repeated incursions of cold air from the north or north-west, giving phenomena similar to those which have been described in recent discussions of line squalls. In the results of Mr. Cave's observations of pilot balloons there is evidence that **V**-shaped depressions at the surface sometimes originate with northerly winds at high levels.

If this is so, our failure to explain the outlines of the distribution of pressure by means of the surface conditions is itself explained. Mr. Dines's recent paper before the Royal Society shows how futile is the endeavour to explain them by reference to temperatures in the layers below 9 kilometres. They come from above, and their shape at any time is governed by causes in the consideration of which we must treat the globe as a whole. Our first step in explaining, for example, the recent succession of gales would be to note whether the westerly circulation in the

region of cirrus clouds had become greatly intensified. We may infer that that circulation depends, at least, in part on the differences of temperature at different latitudes, because the winds are strongest in the winter, when the difference of temperature between the tropics and the pole is greatest; but we cannot yet describe the mechanism of the process nor the variations from year to year. On the other hand, rainfall seems to have to do rather with the small variations of pressure, which elsewhere I have called the embroidery of the barogram, than with the main features of the barogram. Considerations of space prevent my pursuing here the suggestions that this proposition entails. I need hardly say that the subject is not exhausted by what I have said. W. N. SHAW.

November 27.

The Inheritance of Mental Characters.

MR. WALKER sent me, before publication, the letter which appeared in NATURE of November 23. In reply I explained that, though I have insisted elsewhere that the words *inborn*, *acquired*, and *inheritable* are often incorrectly used, yet in my paper to the Eugenics Education Society I did not define the meanings of them, partly because my space was limited and partly because I thought no misapprehension could arise in the minds of my audience. None did arise. But I learn, with surprise, that some would have arisen had my critic been present. I used the words exactly as they are commonly used in biological literature, terming such characters as heads and instincts inborn and inheritable, and such characters as scars and a knowledge of Latin acquired.

In Mr. Walker's book, "Hereditary Characters," he was good enough to reproduce many of my conclusions almost in my own words; for example, "In considering the mental characters of man we are forced to the conclusion that almost all are acquirements, and that very little besides consciousness, memory, capacities for making various acquirements, and a few instincts is inborn." This is precisely my opinion as elaborately set forth, not only "on all previous occasions," but in the very paper he criticises. The astounding thing is that he should imagine that it is, or may be, also the opinion of Prof. Karl Pearson, whose statement, he thinks, "may be loosely expressed and open to misinterpretation," but "which does not appear, on the face of it, to be at variance with his own views." I fear Prof. Pearson will pray ardently to be delivered from his friends.

I must complain that the sentence Mr. Walker quotes from my paper is, in the absence of its context, open to misinterpretation. I was not merely railing. The following is the passage from which it is taken. Prof. Pearson does not use the word "inborn"; but if the word "inheritable" or "physical" be substituted for it, my meaning is unaltered

". . . Here we have an example of a conclusion based, like many more of the conclusions of biometricians, on an ascertained correlation. It is assumed that, since offspring reproduce parental mental characters in the same degree as their physical characters, therefore, if the latter are inborn, the former must be inborn also. In other words, it is assumed that one kind of sameness necessarily involves another and a different kind of sameness."

Now, though I have collected no family histories bearing on the subject, I think that no one will deny that such characters as heads, hearts, lungs, livers, and the like are inborn and invariably present in parents and offspring—at any rate in offspring that reach school age. Here we have absolute certainty of inheritance. Again, I think no one will deny that parental birth-marks, moles, and the like, are also inborn, and that they are hardly ever, if ever, reproduced by offspring. Here the degree of inheritability is zero. Between these extremes of inheritability lie the degrees of inheritability of all the other characters. Some, like ten fingers and ten toes, are reproduced almost as certainly as heads; others, like eye-colour and hair texture, with less certainty; others with still less certainty; and so on, and so on, until we reach characters the inheritability of which is scarcely greater than that of birth-marks and moles. Plainly, then, since the inheritance of inborn characters varies between certainty and zero, Pearson's statement is without significance—void of all content. Founded with such an air of scientific accuracy on statistics and family histories which have such an appearance of scientific precision, it is so vague as to be quite nonsensical. By the use of his method any character you like may be "proved" to be inborn; for, if only you seek conscientiously, you will be sure to find another undoubtedly inborn, which is reproduced by offspring in about the same degree. Thus all English children have heads, and all speak English. If, then, you are satisfied with the method, you may conclude that English speech in English children is "bred, not created." Or, alternatively, that English children acquire their heads—for you are happy in always having these alternatives to choose from.

G. ARCHDALL REID.

Southsea, November 26.

Amedeo Avogadro.

EXACTLY a century has passed away since the eminent Italian physicist Avogadro published the law which, bearing his name, is now familiar to every elementary student of chemistry or physics. Owing to various causes, Avogadro's labours were but little appreciated, and though he occupied a foremost position among Italian men of science the scientific world in general evinced but little interest in his work. Even the indefatigable Kopp failed to realise the importance of his speculations, with the result that his first history of chemistry contained no reference at all to them. Like Carnot's, Avogadro's writings had to await an interpreter and supporter. In this respect, however, fortune proved more than kind, and in his countryman Cannizzaro, Avogadro obtained an illustrious disciple and a brilliant exponent of his doctrine. But while it is true that the name of Avogadro is now widely known, it is no less true that the record of his life seems to have escaped biographers and historians alike, a statement which will be substantiated by a search through the ordinary English works of reference.

Count Amedeo Avogadro di Quaregna came of a distinguished and noble family of Biella, a small town some way north of Turin, in Piedmont. Various members of the family had won fame in the courts or on the field, but the name is unknown to the world at large except through the work of this student of physical science. Amedeo's father, Count Filippo, married Anna Vercellone, of Biella, and on August 9, 1776, their son was born at Turin, the birthplace of Lagrange. In obedience to his father's wishes young Avogadro studied law. He received his diploma on March 16, 1796, and during the next few years occupied positions in various branches of the law offices. In April, 1801, he was appointed secretary to the Prefecture of the Eridano province. His natural inclination for mathematics and physics, however, led him to carry on his studies, and with his brother Felice he wrote, and presented to the Academy of Sciences of Turin, two papers, in 1803 and 1804, the first being on electricity and the second on the nature of metallic salts. For this work the brothers were nominated corresponding members of the academy on July 5, 1804. Amedeo now obtained permission from his father to follow the career of his own choosing, and after a short course of study he became in 1806 a demonstrator at the Royal College of the Provinces. Three years later, on November 7, 1809, he was appointed professor of positive philosophy (physics and mathematics) in the Lyceum at Vercelli, where he remained until 1821. It was during the early years of his residence at Vercelli that he produced the two memoirs which have immortalised his name. Both the memoirs were published in the *Journal de Physique* of De la Methérie. The first, which appeared in 1811, was entitled "Essai d'une manière de déterminer les masses relatives des molécules élémentaires des corps, et les proportions selon lesquelles elles entrent dans ce combinaison"; the second appeared in 1814, and was entitled "Mémoire sur les masses relatives des corps simples, ou densités présumées de leur gaz," &c. Avogadro returned to the same subject in a memoir which he published in 1821, 1826, and in 1849, and he investigated other problems bearing on the same subject. His other researches included questions in electricity, chemistry, electrochemistry, specific heat, and the expansion of bodies.

On October 6, 1821, Victor Emmanuel I. instituted the first Italian public chair of higher physics, and in November Avogadro was appointed to it. Owing to political troubles the post was suppressed two years later, and Avogadro, after a brief interval, was given a post at the Regia Camera dei Conti, where he continued with undiminished activity his cherished studies. In January, 1832, Carlo Alberto restored the chair Avogadro had occupied, but appointed to it the famous Cauchy, who, it will be remembered, had been compelled to leave the Collège de France and his seat in the National Institute of France owing to the Revolution of 1830. Cauchy had been elected, amidst a storm of indignation, to the seat in the institute vacant by the expulsion of Monge, and he was now in his turn suffering the vicissitudes of fickle fortune.

Towards the end of 1833 Cauchy left Turin to take charge of the education of the young princes at Prague, and Avogadro was again appointed to the position for which he was so well fitted. He remained professor of physics until 1850, when he resigned owing to advancing age, and was succeeded by his favourite pupil, Felice Chiò. His scientific work was continued almost to the end of his life; and he died at Turin on July 9, 1856, having nearly reached the age of eighty.

Avogadro's memoirs, numbering some forty or fifty, appeared in the *Journal de Physique*, the *Annales de Chimie et de Physique*, *Brugnatelli's Journal*, and other periodicals. Among his works was a huge compilation of 3700 pages, in four volumes, on physics, which was published at the expense of Carlo Alberto. His principal studies, as we have seen, related to the physical properties and the internal structure of bodies, and the law—that equal volumes of gas contain the same number of molecules—to which his name is attached perpetuates his memory. Ampère independently enunciated the same doctrine; but in point of priority Avogadro's claim is beyond dispute.

He was a man esteemed in private life for his kindness, affability, and sincerity. His habits were noted for their simplicity, and he was as modest as he was learned. The year following his death a marble bust in his honour was placed in the University of Turin. In the Scuola Professionale at Biella is another bust, with the inscription—

I GAS A PARI CONDIZIONI
DI PRESSIONE E DI TEMPERATURA
IN EGUALI VOLUMI CONTENGONO
UN EGUAL NUMERO DI MOLECOLE.

Last year a project was formed to celebrate the centenary of the enunciation of his law, but I do not know whether the scheme was carried through or not.[1] The above details have been obtained from the short biography of Avogadro by Alfonso Cossa, for a copy of which I am indebted to the kindness of Prof. Naccari, the present occupant of the chair of physics at Turin. EDGAR C. SMITH.

Hong Kong, October 23.

Characteristic Röntgen Radiations.

In the September number of *The Philosophical Magazine* there appears a paper by Prof. Barkla, in which are tabulated the results of some further experiments on characteristic (fluorescent) Röntgen radiations. It appears that some of the elements of high atomic weight give "two lines in the fluorescent spectrum." Optical analogy suggests that there may be some simple relation connecting these spectral lines. Such a relation can, indeed, be readily obtained, and I should like to be allowed to direct attention to it.

In a paper on the production of characteristic Röntgen rays (Roy. Soc. Proc., 1911), I showed that for the elements from Al upwards (which gave characteristic rays in series K) the radiation they emitted could be defined, indirectly, in terms of their atomic weight. It was shown that the radiation characteristic of an element of atomic weight w is the same (when tested by penetrating power) as the most penetrating of the Röntgen rays emitted from an antikathode bombarded by kathode rays of velocity equal to kw, where $k=10^8$.

Thus the radiation characteristic of Se would be emitted by kathode rays of velocity $7{\cdot}92\times10^9$ cm./sec. ($w=79{\cdot}2$), that characteristic of Cu by kathode rays of velocity $6{\cdot}36\times10^9$ cm./sec. ($w=63{\cdot}6$), and so on. Such kathode rays as would produce a characteristic Röntgen-radiation may be conveniently termed equivalent kathode rays. Thus we can define a radiation the λ/ρ of which is known, in terms of the velocity of the equivalent kathode rays, and so indirectly in terms of the atomic weight.

Prof. Barkla tells us that Bi gives out (in series L) a radiation of very nearly the same penetrating power as that from Se in series K (the actual values of λ/ρ are 19·0 and 18·9). From this it follows that the equivalent velocity for Bi (series L) is the same as for Se (series K), *i.e.* $7{\cdot}92\times10^9$. Thus, if we adopt series K for our standard, we can say that Bi behaves (for series L) as though it were an element of atomic weight 79.

The actual atomic weight of Bi is 208, and it behaves (for series L) as if its atomic weight were $w'=\frac{1}{2}(w-50)=79$; thus the two possible spectral lines for Bi are defined in terms of the two equivalent kathode rays of velocities $2{\cdot}08\times10^{10}$ cm./sec. and $7{\cdot}9\times10^9$ cm./sec.

The expression

$$w'=\tfrac{1}{2}(w-50)$$

holds fairly well over the greater part of the range studied by Prof. Barkla, as the following table shows.

Element	w	w'	λ/ρ (calculated)	λ/ρ (observed)
Sb	120·2	35·1	375	435
I	126·9	38·5	298	306
Ba	137·4	43·7	248	224
W	184·0	67·0	35·0	33
Pt	195·0	72·5	25·5	27·5
Au	197·2	73·6	23·8	25
Pb	207·1	78·6	20·0	20
Bi	208·0	79·0	19·1	19

The calculated values of λ/ρ have been obtained by interpolation of w' in a w, λ/ρ graph.

The observed value of λ/ρ for Sb is almost certainly too high, since in some experiments with Sb (August, 1910, Proc. Camb. Phil. Soc.) I found that the equivalent velocity was about $3{\cdot}6\times10^9$ cm./sec. (compare w' above). The agreement otherwise is as good as could be expected.

In conclusion, formulæ of the type to which attention has just been directed ($w'=A.w+B$) may possibly prove useful to experimental investigators in suggesting new "lines" and indicating where to look for them.

R. WHIDDINGTON.

St. John's College, Cambridge, November 16.

A Suggested Reform in Palæobotany.

In a paper in the *Annals of Botany* for October (pp. 903–7, text figures) I brought forward conclusive botanical evidence that the Cretaceous fossils from the Amboy Clays of North America, hitherto known as *Ophioglossum granulatum*, Heer, are not only not Ophioglossums, but are not ferns at all, and belong to the widely distinct family of Gymnosperms, in the genus Pinus.

This result, in itself of not much importance, forms the text of a general recommendation to palæobotanists, which is as follows:—In the interests of the sciences of palæobotany, geology, and botany, I "urge that the lists published by palæobotanists should be printed in two forms, and that the names of species of leaves, stems, &c., of which there is a reasonable security of determination, should be differentiated from those in which there is no guarantee at all that the actual nature of the plant has been discovered. Any tri-nomial system is cumbrous; but those who publish on fossil plants might print their names in type of two kinds, which would indicate which species are doubtful. I should like to suggest that, instead of using italics or ordinary capitals as is usual in printing the names of species and genera, such doubtful plant-impressions should be printed in Gothic lettering. This would indicate that our knowledge about them is mediæval —of the Dark Ages—and would further save the inconvenience of tri-nomials, while it would indicate immediately the difference between the established and the doubtful determinations. As information accrued about a

specimen it could easily be transferred to the clear Latin italics.

"Thus the transference of Ophioglossum granulatum, Heer, to *Pinus granulata* (Heer) would indicate that an exceedingly doubtful determination had been replaced by one with some scientific basis. Any worker in another branch of science, seeing O. granulatum, in Gothic, would be warned at least to look into the grounds for the determination for himself before he—let us imagine—used the record for his stratigraphic work in correlating horizons, or in writing up the early history of the Ophioglossaceæ, when he would otherwise assume that the living genus was represented in Cretaceous times in the Ambay Clays of North America. This is merely an illustration of what is very widely spread in fossil botany; but it may serve to give point to the general proposition that the time has come when it would be of real service to the science to attempt a conscientious distinction between valuable and doubtful determinations, and that Gothic lettering might give us an easy indicator.

"The need for this is all the greater, because the results of palæobotany touch so many other fields of research, in animal palæontology, geology, and palæogeography, as well as botany itself. Workers from these other fields are seldom able to estimate the evidence that they are taking to build into their own work, even had they the time to go into the details; and thus a single error gets widely disseminated. Often it is not entirely the fault of the one who originally described the fossil, for he may say in his text that the nature of the specimen is doubtful, and that, in default of better evidence, he gives a certain name with hesitation. That name, however, once given, is quoted and put into lists without being in any way distinguished from the rest; and the results are detrimental to the advance of true knowledge in every way. It is no solution to call every leaf, as some conscientious workers do, 'Phyllites': different things, however doubtful, must have distinct names, and the use of Gothic characters for the very doubtful ones would greatly tend to 'create confidence' in the science of palæobotany."

MARIE C. STOPES.

The Unit of Momentum.

DOUBTLESS all teachers of experience are agreed that in dealing with the measurable quantities considered in mathematics and physics there is great difficulty in giving to students a clear idea of the quantities measured unless a definite name be given to the unit in terms of which measurement is made.

Until the word "radian" was introduced, circular measure was a stumbling-block to all beginners in trigonometry; the sentences "the circular measure of this angle is 1·7" and "arc over radius equals 1·7" make little impression on the untutored mind; but the sentence "this angle contains 1·7 radians—the radian being rather more than 57°" is as easy of comprehension as "the value of this is $2\frac{1}{2}$ guineas—the guinea being 21 shillings." So in electricity, without the names ampere, volt, ohm, &c., the learner would be—as he was thirty years ago—lost in hopeless vagueness.

In mechanics we have given names to almost all the units; why not give one to the unit of momentum? I venture to suggest for general use the names which I have myself made use of for many years, and have found helpful in inducing clear thinking on the part of my students; they are analogous to the names of the units of work.

Thus the work done by a force 1 lb. acting for 1 ft. is one ft-lb.

The momentum produced by a force 1 lb. acting for 1 sec. is one sec-lb.

The work done by a force 1 poundal acting for 1 ft. is one ft-poundal.

The momentum produced by a force 1 poundal acting for 1 sec. is one sec-poundal.

The work done by a force 1 dyne acting for 1 cm. is one cm-dyne (erg).

The momentum produced by a force 1 dyne acting for 1 sec. is one sec-dyne.

Similarly we may speak of a sec-ton and a sec-tondal.

The advantage of the above names is that they emphasise the essential distinction between momentum and kinetic energy, viz. that one measures what I may call the time-effect of a force and the other its space-effect; or, to put it differently, when we know the momentum of a moving body we know *how long* a given force must act to produce the motion, and when we know its kinetic energy we know *how far* the force must act. This point of view seems to me far more desirable than the suggestion to the beginner that momentum is mv, or "mass × velocity"; such a suggestion he must either receive in deadly apathy or he must worry his brain with the impossible task of trying to conceive how mass can be *multiplied* by velocity: his teacher may try to slur over the difficulty for him by a word-juggling substitution, and say momentum is the *product* of mass and velocity; but then, what is a product? In the mathematical sense of the word it is the result of multiplication; in the non-mathematical sense it is anything resulting from or produced from certain others; and in this latter sense kinetic energy is just as much the product of mass and velocity as momentum is. So, also, the time-honoured but vague phrase "quantity of motion" could be used to express kinetic energy with quite as much aptness as to express momentum.

Using these names, we would teach—

"The momentum of m lb. moving at v f.s. is mv sec-poundals, or mv/g sec-lbs.; its K.E. is $\frac{1}{2}mv^2$ ft-poundals, or $\frac{1}{2}mv^2/g$ ft-lbs." "The momentum of m grams moving at v c.s. is mv sec-dynes; its K.E. is $\frac{1}{2}mv^2$ ergs (cm-dynes)."

F. R. BARRELL.

The University, Bristol, November 7.

I AM in the habit of saying, "the amount of momentum is 12 in C.G.S. units" or "the amount of momentum is 12 in engineers' units." The use of such a complex name as "gram-centimetre per second" would be absurd. Now Mr. Barrell has made an excellent suggestion; the names sec-dyne with all students, and sec-pound with such students as use engineers' units, are not only short and easy to remember, but they keep before the student the fundamental fact that force is time rate of change of momentum. It seems to me, however, that at the start we must define momentum as mv, and boys must from the start learn that they are no longer multiplying mere numbers. I never found that a boy had any difficulty if his master did not create one. A boy knows at once that if a distance of 100 yards is passed over in 20 seconds there is an average speed of 5 yards per second; he has no difficulty in dividing space by time, but his teacher may create great confusion in his mind if he philosophises about it.

JOHN PERRY.

Fish and Drought.

IN my letter on "Fish and Drought" published in NATURE of November 23 there is an error, due, without doubt, to a mistake in my MS., which may confuse the reader. In the tenth line from the bottom of the right-hand column of p. 108 the word "north" occurs; it should read "south."

It has been pointed out to me by friends who have read the letter that the final paragraph is rather difficult to follow. With your permission I beg to take this opportunity of rectifying its expression, as follows:—

In conclusion, I think that the observations above recorded show that the material of geological formations need not necessarily have been "laid down"; it may have been produced *in situ* like the mud in the ditch round the Park of Marchais, and that the enclosure in it of animal remains may have been in some cases due to a voluntary act of self-inhumation, undertaken, perhaps usually, with a view to self-protection. They also show that two neighbouring strata, the one carrying abundance of life and the other being destitute of it, may nevertheless be contemporaneous in date and conterminous in locality of formation.

J. Y. BUCHANAN.

November 26.

THE INTERACTION BETWEEN PASSING SHIPS.

ONE of the prominent questions of the day in naval architecture circles is that of the influence of passing ships upon each other. It has been known for many years that such an influence exists between vessels in confined waters, canals, for example, and for such canals there are usually stringent regulations as to speed and manner of passing of ships. Such conditions are, of course, extreme, but the narrowness and shallowness of the canal, merely intensify a phenomenon which is present in deeper or broader waters, but not always apparent.

tendency for it to cant in towards two; in the second position the forces are all tending to draw the two ovals together, there being throughout the body of water between them less pressure than exists on their outer sides. In the third case, oval one is subjected to forces tending to cant it towards or away from two, as the stern is in a field of pressure below normal on its nearer side, and the bow in a field of increased pressure on the inner side.

The extent and importance of these forces will depend on the lateral distance apart, on the bounding conditions of the fluid, and on the speeds, both absolute and relative, of the ovals. In order to give an indication of how greatly this influence is increased

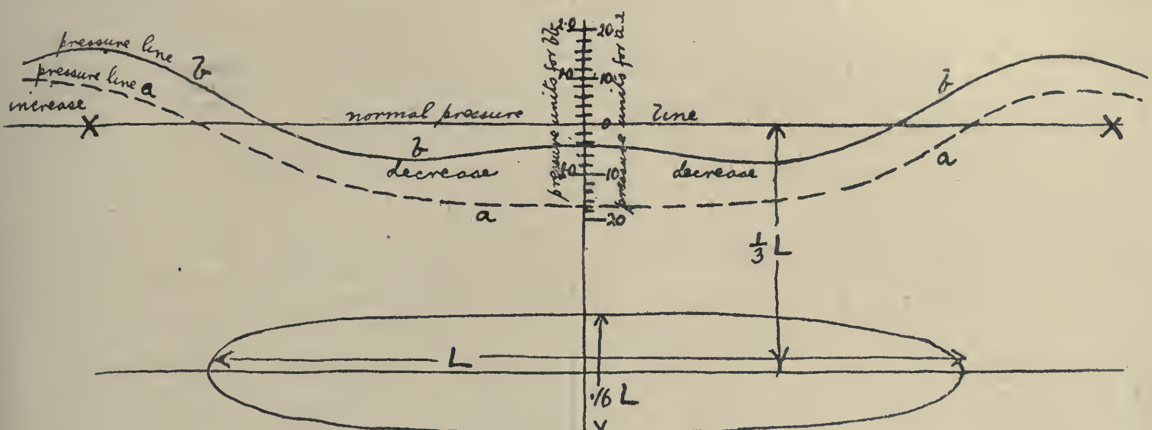

FIG. 1.—Variation of pressure around an oval along the line X X.

A ship's form unfortunately cannot be expressed by any formula, and its stream lines cannot be easily calculated, but by considering the case of two ovals formed by "sources and sinks," we can get a rational idea of the character and variation of the forces which come into play. The equation for the pressure at any point in the fluid surrounding an oval is given by:—

$$-\frac{p}{w}=\frac{v^2 f}{2g}\left[\left(\frac{\cos\phi_1}{r_1^2}-\frac{\cos\phi_2}{r_2^2}\right)+\frac{f}{4}\left(\frac{1}{r_1^4}+\frac{1}{r_2^4}-\frac{2\cos(\phi_1+\phi_2)}{r_1^2 r_2^2}\right)\right] \quad (1)$$

where r_1, ϕ_1 and r_2, ϕ_2 are distance and angle from source and sink respectively, and f varies with the distance between source and sink and length of major axis, and v^2 is the relative velocity of fluid and oval.

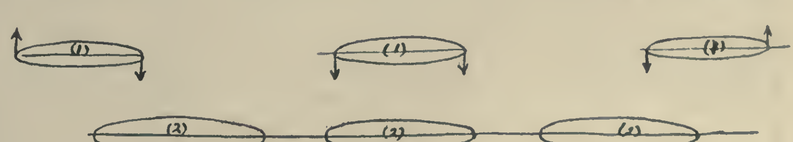

FIG. 2.—Action between passing ovals.

The line b b in Fig. 1 shows the variations of the pressure from the normal, along a line distant one-third the length from the centre line, and it can be seen from this that, speaking generally, there exist at each end of such an oval fields of increased pressure, and that the space between them is a region of diminished pressure.

If two such ovals are moving in the fluid, it can be readily seen that the variations of pressure due to one will modify the pressures due to the other, and that the pressure conditions on the sides of the ovals nearer to each other are different from those on the outer sides.

In Fig. 2 the ovals are shown in three positions relative to each other, and the arrows at each end of oval one show the motion which the forces due to interference tend to set up. If one is overtaking two, in the first position shown, there will be a strong

when a body moves from deep to shallow water, the curve a a has been drawn in Fig. 1. This shows the variation of pressure for a plane oval (*i.e.* with two-dimensional flow), having the same axes as the oval for which curve b b has been drawn, and it will be noticed that the scale of a a is one-tenth that of b b.

Such general reasoning, however, although showing the nature of "interference," does not give a measure of the forces involved with actual ship forms under similar conditions, and to obtain this experiments must be made with models in water of different depths.

Experiments conducted in 1898 in a German canal with barges having a sectional area approximately one-third the sectional area of the canal, showed a region of considerable excess pressure in front and at the rear of the barge, and on the bank for the whole length of the barge a remarkably strong negative current or diminution of pressure.

The experiments made by Naval Constructor D. W. Taylor in the Washington Tank, throw a considerable light on the problem. The ship-shaped models used were of the same length and were run at an average speed corresponding to 13·5 knots for 500-feet ships.

The results of the experiments show that in very deep water such ships do not begin to influence each

other appreciably until their distance apart is less than 0·8 of their length, and that this influence is becoming very noticeable when the distance apart is 0·6 of their length. It was also found that, with the models in any given position, the forces involved varied as the resistance of the models, *i.e.* for these speeds roughly with the square of the velocity as theory would lead us to expect.

The variations of the forces as one model was moved to varying fore and aft positions relative to the other (keeping the lateral distance the same) showed the very strong tendency which any model had to cant into the stern of the other model which it was overtaking, how this tendency to cant changed, as the models were brought abreast each other, to a strong sheer of each model towards the other, and, finally, when one model was shifted so that its bow was well forward of the bow of the other, it had a strong desire to cant away from the latter. This is all much the same as the consideration of our two ovals has led us to expect, and goes to show that passing vessels, even in deep water, are liable to exert strong forces upon each other. If they are moving at approximately equal speeds in the same direction, *i.e.* if the forces are maintained for a considerable time, then these forces will tend to produce erratic movements of the ships, requiring careful navigation if a collision is to be avoided.

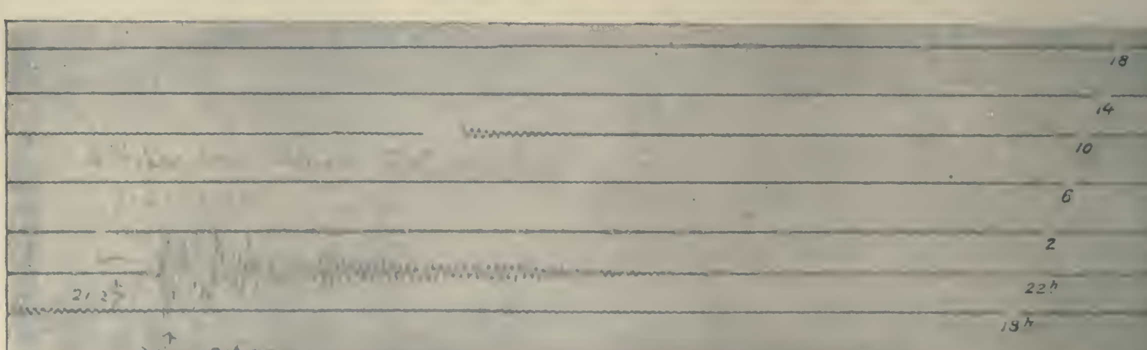
No experiments have been made up to the present to test this suction or interference in shallow water, except those made recently at the National Experiment Tank at Teddington in connection with the *Hawke* and *Olympic* collision; but the general reasoning already given is good ground for supposing that such influence would be greatly magnified as a vessel passed from deep to shallow water.

THE CENTRAL EUROPE EARTHQUAKE, NOVEMBER 16, 1911.

ON the night of November 16, at 10.25, western Germany, eastern France, and Switzerland were rudely shaken by an earthquake of exceptional intensity. At Frankfort-on-Main houses were cracked. In Freiburg, Stuttgart, Munich, Mülhausen, and in other towns, chimneys and roofs were damaged. The valley of the Upper Rhine was shaken throughout its length. At Constance two colossal statues fell from the Post Office upon the pavement. According to reports in the daily papers, walls were split, church spires were wrecked, roofs were shattered, people were "thrown out of their beds," telephone and telegraph communications were destroyed, and the path of the earthquake was marked by ruin from Magdeburg to Berlin. Everywhere terror-stricken people "rushed" from their houses, and at Ebingen 500 of its inhabitants gathered round a fire during the night and recounted their weird experiences.

It is difficult to reconcile these descriptions of widespread ruin with the fact that there does not appear to have been a single casualty. One thing about which we can be certain is that the earthquake was felt eastward to Erfurth, westwards to Nancy, and southwards to Milan. At least 17,000 square miles of Central Europe received a shaking perceptible to the greater number of its inhabitants. Outside this area it was recorded by many seismographs. Whether the disturbance was or was not recorded in very distant places largely depends upon the character of the instrument employed to record teleseismic motion. Experience has shown that seismographs recording photographically pick up these effects at greater distances from an epicentral area than those which register mechanically.

The accompanying seismogram of east and west motion, as recorded in the Isle of Wight, shows that the disturbance commenced at 9h. 27m. 30s., and reached a maximum two minutes later. The inference from this is that the origin was 5 degrees or 300 geographical miles distant. That it was a near earthquake is also indicated by the rapidity of the vibrations. At the distance indicated we reach the upper part of the Rhine Valley, a district from Frankfort, through Bâle to Constance, well known to seismologists as an earthquake-producing region. In a popular sense the upper part of this is a valley, but from the manner in which it originated it is sometimes referred to by geologists as a *graben*, or piece of territory that has fallen downwards between two faults. In this instance one of these faults borders the Vosges and the other the Black Forest. It is a tectonic displacement along which adjustments from time to time have taken place, each of which represented a relief of strain and was accompanied by a shaking. One well-known paper solemnly informs its readers that this earthquake was of Teutonic origin, and, considering the country in which it was made, the statement may be regarded as correct.



At present it cannot be said with certainty that this disturbance originated from the chief of these tectonic lines or from one of their numerous offshoots. To the right and the left of the Rhine Valley the country is cracked through and through with many minor fractures, a sudden movement on any one of which might be capable of producing all that has been observed.

J. MILNE.

DUST EXPLOSIONS.

THE explosion of a mixture of dust and air, supposed by the head of the firm of Messrs. Bibby Brothers to have been the initiating cause of the catastrophe which destroyed and set on fire part of their oil-cake and seed-crushing mills in Liverpool on the night of November 24, is the most probable explanation of that occurrence. It appears that some of the seeds which contain no oil form an exceedingly fine powder when crushed. The hypothesis is that fine powder produced in this manner became disseminated in the air of the chamber, thus forming an inflammable mixture, and was ignited by some means not ascertained, possibly by a stream of sparks due to friction between the grinding rolls, possibly by an open light. Be this as it may, a violent explosion took place, shattering that portion of the mill in which crushing is carried on, and causing the deaths of thirty-one persons, and, more or less, serious injuries to 112 others.

This event recalls the disastrous explosion which destroyed the Tradeston Flour Mills in Glasgow in 1872, and was investigated and reported upon by Profs. Rankine and Macadam. On that occasion Prof. Macadam stated: "When the whole of the conditions required theoretically for the most disastrous explosions are practically realised, the increase of pressure is equal to eight atmospheres, or 120 lbs. per square inch, which must necessarily bring about a violent explosion and wreck any ordinary building."

Another notable explosion of the same kind, which stands unrivalled in the magnitude of the havoc wrought by it, wrecked the Washburn Flour Mills at Minneapolis on May 2, 1878, and set fire to six other mills and a number of buildings in the neighbourhood. Profs. Peckham and Rye, who were commissioned by the coroner's jury to investigate the circumstances in which it took place, made a series of experiments in closed boxes to test the explosibility of a variety of powdered substances, amongst others various flour mixtures and coal dust. The powders were blown into the box with bellows and ignited by an open light. As the result of their experiments the investigators came to the conclusion "that practically all finely divided highly carbonaceous material would explode under the conditions tried."

Explosions in grinding mills are not, perhaps, so infrequent as might be imagined: a dust explosion occurred in an adjoining block in Messrs. Bibby's mill four years ago, when several workmen were injured, and many similar explosions have taken place in flour mills from time to time, causing damage and setting fire to the buildings, but not heard of beyond the immediate locality, and then probably reported merely as fires.

Most mill owners seem to be now alive to the risks they run from this cause, and take the precaution of limiting the dimensions of the spaces in which mixtures of dust and air are necessarily formed, and excluding open flames from them. Besides flour mills, sugar refineries, starch works, and factories for the preparation of madder, lycopodium powder, flour of sulphur, and so on, have all been the scenes of explosions of this kind. Lycopodium powder, which consists of the spores of *L. clavatum*, the stag-horn moss, is amongst the most inflammable of these substances. It burns with a sudden flash of yellow flame and with a hissing noise, probably due to the bursting of the individual spores, when its mixture with air is ignited.

Lastly, the inflammable, and under certain conditions explosive, nature of a mixture of air and coal dust is now becoming better understood and appreciated, and has recently constituted the subject of articles contributed by the present writer to the pages of NATURE (vol. lxxxvi., pp. 223, 595).

W. GALLOWAY.

THE TEACHING OF MATHEMATICS.[1]

THESE two reports on mathematical teaching cover very different ground, and are treated from very different points of view. The report of the London County Council refers particularly to elementary schools, though in many places it deals with general questions of mathematical teaching that apply to schools of all types. The New South Wales report refers entirely to the work of secondary schools. Again, the L.C.C. report is drawn up by a body consisting mainly of teachers in the closest touch with the child, and, throughout their report, they consider the state of development of the child's mind and the wide differences there must be between the children in the future. In marked contrast to this, the N.S.W. report does not seem to be based on an intimate knowledge of the minds of average pupils, but seems to aim only at the production of future mathematicians.

The L.C.C. report opens with a chapter devoted to general questions of mathematical teaching; then follows an excellent chapter on the first steps in arithmetic. The next chapter, "On the coordination of arithmetic with science and other subjects of the curriculum," is the most suggestive chapter in the report; there are many excellent suggestions for changing the arithmetic lesson from a dull grind to a really attractive lesson, instilling into the pupils a truly scientific spirit. The only doubt that arises in our mind is whether the second-rate teacher will keep a proper balance between the illustrations leading up to new ideas and the new ideas themselves—recent experience in geometry shows that a word of warning is necessary. The fourth chapter deals with the logical and computative sides of the subject—some of the examples considered seem to be the diabolical inventions of the examiner or the text-book writer. Finally, we have a summary of the answers to questions sent round to teachers, examiners, and inspectors—some of these are of great interest; the most interesting perhaps is taken in the first chapter; it deals with the "relative capacity of boys and girls for mathematics":—

> "Opinions expressed were in favour of a greater general capacity for mathematics, especially as tested by the solution of problems, among boys, and of greater neatness, accuracy, and conscientiousness in carrying out rules and processes, among girls. It was, however, stated that many brilliant exceptions were to be found amongst the girls. The evidence further went to show that the genius is balanced by the dullard more often among groups of boys than among groups of girls."

Altogether, the report is one of the most suggestive contributions that have been made to the literature on mathematical teaching in schools. We commend it most heartily to all teachers in secondary as well as elementary schools.

In the N.S.W. report there is a paragraph near the beginning which lays stress on the importance of coordination in teaching the various branches of mathematics, but it is not worked out in detail, and seems to break down in one or two places; *e.g.* in the second year trigonometry is included under arithmetic, whereas

[1] London County Council. Education Committee. Report of a Conference on the Teaching of Arithmetic in London Elementary Schools. December 1906–December 1908. Pp. 134. (London: P. S. King and Co., 1911.) Price 1s.

Memorandum on the Teaching of Elementary Mathematics. By Prof. H. S. Carslaw. Pp. 31. (Sydney, N.S.W.: Issued by the Department of Public Instruction, n.d.)

trigonometry, including the definitions and numerical work, is not begun until the third year. In arithmetic stress is laid on the importance of a grasp of principles, and reference is made to the harm text-books have done in the way of multiplying rules and setting up mere trivial examples as important types. We do not know the average age of entry to the secondary schools of N.S.W., but we doubt whether pupils in their first year are sufficiently mature in mind for such questions as "Retail and Banker's Discount" and "Balance Sheets." In England arithmetic has suffered seriously by the introduction of the technicalities of commerce and the money market at too early an age. The second-year course is to go deeper into such things; we should have thought it wiser to postpone most of this work to the third or fourth year, and bring in more numerical trigonometry and easy mechanics to take its place—it is intended to do something of the sort in the second year as "simple problems on the lever, wheel and axle, and inclined plane" are included, but there are no suggestions as to the practical work on which to base these problems.

The section devoted to algebra begins with a philosophical treatment of negative and fractional quantities, but it is not proposed that pupils should be taken through such a treatment "in their first steps in algebra"; but the course suggested for the first two years is what schools in England have been trying to break away from in the last decade. The whole attitude seems to be too abstract for beginners—we should have liked to see the factors of x^3+a^3, long H.C.F., and the solution of two simultaneous equations, "in which only terms of the second degree and constant terms occur," all postponed until after the second year, and indices and logarithms brought back in their place. We feel that it would have been wiser to make the early treatment much less abstract and more numerical, and to let the fourth-year course include a more scientific treatment of the elements of the subject.

Differential calculus is introduced into the fourth year's algebra, but seems to be intended only for those who matriculate in higher mathematics. We should like to see a short introduction to both differential and integral calculus introduced into secondary schools for all pupils of average ability. The treatment suggested in this report for the differential is good, including, as it does, the principles of the subject without elaborating the technique—we suspect that integral calculus is meant to be included as reference is made to the evaluation of areas, &c.

The report goes on to discuss geometry:—

"It is common knowledge that within the last few years the methods adopted in the teaching of geometry have been greatly altered. No less common is the belief that many of the changes which have been made have hardly justified themselves, that the relative importance of the various parts of the subject has been frequently forgotten, that much unsatisfactory reasoning is being accepted as logical, and that much unnecessary confusion exists. . . . A boy who has made a comparatively close acquaintance with straight lines, angles, circles, triangles, parallelograms, &c., by actual drawing and measurement, knows far more of their properties than one who has learnt by heart long lists of definitions and some of Euclid's propositions. And when, by a carefully graduated series of experiments and drawings, he has discovered for himself the fundamental theorems regarding congruent triangles, the theory of parallels, the measurement of areas, and the circle, he is ready to proceed to the study of deductive geometry, and should profit by that study in many different ways.

"This is the first, and one of the most important, of the changes which have been made in the teaching of geometry; but, with regard to it, some words of warning are still necessary. There is no doubt that the *rôle* of experiment, careful drawing, exact measurement, and calculation from the figures drawn by the pupils has been exaggerated."

With all this we agree most heartily, but with Prof. Carslaw's remedy we cannot agree; this practically amounts to taking the theorems of Euclid to the end of parallels, and setting them up as a standard order to be followed by all schools. Prof. Carslaw seems to feel that such a retrograde step is likely to meet with opposition, for he says: "Without prescribing rigid adherence to the scheme drawn up and embodied in its programme, the Department intends to base its instruction upon it." This seems to give the teacher the choice the famous Hobson gave to his customers when they came to hire horses. We can only express our deep regret that such a retrograde step should be deemed necessary in N.S.W. to remedy an evil which is doubtless the same in all its features as that we are experiencing in England.

The evil may be considered to be due to two distinct causes: (i) some teachers have not shown a proper appreciation of what constitutes a sound logical proof, and have let their pupils use slipshod arguments; (ii) pupils have a break in their careers when they pass from the elementary to the secondary schools. With regard to (i) it may be pointed out that practically all teachers, both in England and Australia, have had their training in geometry under a cast-iron system, viz. that of Euclid; some teachers under that system have acquired a splendid appreciation of what is logical, but the very existence of the evil referred to proves that other teachers have not acquired that appreciation—this does not point to finding the remedy in another cast-iron system, particularly one closely following the lines of Euclid.

Doubtless a rigid system would remedy the difficulty of transition from school to school, but that difficulty ought never to exist; for, as Prof. Carslaw points out, the only trouble due to the lack of a standard order lies in the fundamental theorems about congruence, and parallels and the angle-sum for a triangle; and that part of geometry, in our opinion, should not be treated deductively before the age of fourteen with any but pupils of very exceptional mathematical ability, and possibly not with them. It will be remembered that a couple of years ago the Board of Education published a circular recommending that these fundamental theorems be arrived at by induction, and then taken as a base on which to build up a logical system of deductive geometry. Prof. Carslaw says:—

"With this advice I find myself unable to agree. One of my reasons for disagreeing with their method is that I am sure the difficulty that these fundamental congruence theorems offer to the pupil is exaggerated, and that I believe the reasoning, by means of which they are to be proved, can be of value to him. Another ground for my dissent from the plan of that circular is that the treatment of parallels which it recommends, by its introduction of the idea of direction as fundamental, and by making the angle-sum theorem independent of the theory of parallels, includes one of those fallacies with which the long history of that theory is crowded."

We wonder whether Prof. Carslaw has seen the advice of the Board carefully followed by sympathetic teachers; it is generally found that the results of teaching on these lines are much better than those where a deductive treatment of congruence, &c., is attempted—there is greater knowledge of geometry, greater appreciation of logical geometry, and more power to tackle new work. We must differ from Prof. Carslaw when he says the difficulty of the congruence theorems is exaggerated—in a comparatively wide experience of boys, we have never found the proofs of these theorems clearly understood until the boy has

had some further acquaintance with deductive geometry in the form of riders and later propositions, though in many cases the proofs have been learnt for purposes of reproduction.

Again, Prof. Carslaw objects to the use of the idea of direction in dealing with parallels and the angle-sum theorem—we should quite agree with him that such a treatment would not be satisfactory in a deductive course, but we differ most strongly from him in thinking that a deductive treatment of parallels, &c., is necessary or wise in the first two years of geometry. The fact is, deductive geometry is not a suitable study for children before the age of twelve, and even at that age it must be a difficult study, and the deductive treatment of congruence and parallels is one of the most difficult parts of the subject, and should certainly not precede the deductive treatment of the parallelogram and the circle. We can only regret that New South Wales has been frightened by difficulties which were bound to arise in a period of transition, into going back to the old methods instead of boldly remedying the evil by helping all teachers to get the spirit of the new methods.

The report goes on to consider trigonometry and mechanics, but there is nothing that calls for serious comment. R. Y. S.

TSETSE-FLIES AND SLEEPING SICKNESS.

A DEPUTATION representing eight missionary societies at work in Nyasaland waited upon the Secretary of State for the Colonies on November 23 in order to urge that game restrictions should be removed over a whole or part of the protectorate, on the ground that the tsetse-fly was suspected of spreading sleeping sickness, and that the destruction of big game "might" eliminate the fly. In his reply, Mr. Harcourt very wisely deprecated hasty action in a matter in which "the best-informed people were the least positive as to the facts."

It is by no means certain that the destruction of the larger mammalian fauna would have any such effect as the members of the deputation seem to anticipate. In the first place, it is highly probable that the primary host of the trypanosome of sleeping sickness is man, and that if the trypanosome is now to be found in wild mammals in regions in which the disease is known to have been introduced in recent times, it is because it has been transmitted to them from human beings by the agency of the tsetse-flies. Secondly, it is very far from certain that the destruction of the larger mammalia would have the effect of eliminating tsetse-flies, which can suck the blood of any kind of vertebrate animal, and which swarm in parts of the Uganda Protectorate (for example, on small uninhabited islands in the Victoria Nyanza) where there are no larger mammalia. Thirdly, the danger must be reckoned with that to deprive the tsetses of a large portion of their natural food-supply might have the effect of forcing them to supplement the deficiency elsewhere, and might therefore render them much more aggressive towards men and domestic animals, and in this way more efficient in spreading trypanosome diseases.

Everyone with a knowledge of the complicated problems involved in the subject of the transmission of trypanosomes by tsetses will deprecate ill-considered destruction of the big game, an action which, while robbing large tracts of country of one of their most beautiful and valuable features, may very well have the effect of upsetting the balance of nature in a manner that would greatly aggravate the evils which it is desired to combat.

THE INTERNATIONAL CONFERENCE AT PARIS ON NAUTICAL ALMANACS.

ON the initiative of the Bureau des Longitudes, the directors of the various national ephemerides were invited by M. Baillaud, director of the Paris Observatory, to assemble there on Monday, October 23. The objects of the reunion were to consider what steps, if any, should be taken to extend the scope of the various ephemerides for the purposes of astronomy, and at the same time to effect economy by combined action and interchange of computations. A small number of the leading practical astronomers were also invited to represent the needs of astronomy of precision.

The first general meeting was held at the Observatory at 10 a.m., Monday, October 23. On the motion of Sir David Gill, M. Baillaud took the chair, having on his right M. Bayer, secrétaire de l'enseignement supérieure, representing M. Steeg, Ministre d'Instruction publique.

On the motion of M. Baillaud, Sir David Gill, as président d'honneur du Congrès de la Carte du Ciel, was nominated président d'honneur of the reunion, Dr. O. Backlund, imperial astronomer of Russia, vice-president, and Mr. H. Andoyer, of the Bureau of the Connaissance des Temps, together with the Comte de la Baume Pluvinel, were nominated secretaries. There were present:—Prince Roland Bonaparte (member of the Academy of Sciences); Messrs. Cowell ("Nautical Almanac," London), Fritz Cohn (Berlin), Eichelberger (Washington), Général de Azcarate (San Fernando), Boccardi (Turin), as directors of ephemerides; Messrs. Dyson (astronomer royal, Greenwich), Hough (H.M. astronomer, Cape of Good Hope), Perrine (Cordoba), André (Lyons), Picart (Bordeaux), Verschaffel (d'Abbadia), as directors of observatories; and, as representatives of the Bureau des Longitudes, MM. Bigourdan (president), Poincaré, Radau, Deslandres, Hanusse.

The meeting was opened with an admirable address by M. Baillaud, and with a cordial speech of welcome by M. Bayer on behalf of the Minister of Public Instruction. After some discussion, resolutions, recommending the adoption as soon as possible of Greenwich mean time as the argument for all predictions in nautical and astronomical ephemerides, were unanimously passed. In the afternoon of the same day the members of the congress attended by invitation the meeting of the Academy of Sciences at the institute, and in the evening were entertained at a banquet in the Observatory, at which M. Steeg, Minister of Public Instruction, was present. The toast of "The President of the French Republic" was proposed by Sir David Gill, to which an interesting and eloquent speech was made, in reply, by M. Steeg. The health of M. Baillaud was proposed by Dr. Backlund.

Further meetings of the congress were held on October 24 and 25, and at the conclusion of the meeting on October 25 a unanimous agreement on all points was reached. On Thursday, October 26, the directors of the nautical almanacs met in committee to make final cooperative arrangements and report to the general congress; their report was unanimously adopted at an afternoon meeting on the same day.

A translation of the resolutions adopted is subjoined. It is impossible to overrate the good will and cordiality which pervaded the meeting, or the kindness and hospitality of our hosts. Besides the official banquet on Monday, private dinner-parties were given by M. Andoyer on the Tuesday, by M. Baillaud on the Thursday evening, the latter followed by a reception; a luncheon and reception were also given on the Friday afternoon by Prince Roland Bonaparte, and

boxes at the theatre and Opéra were placed at the disposal of members of the congress.

The results of the congress promise to be of great interest and value, not merely by extending the scope and utility of the national ephemerides for the purposes of practical astronomy, but by the facilities which the universal adoption of Greenwich time offers for the comparison of the different lunar and planetary tables.

A probable sequence to these resolutions will be the universal adoption of Greenwich as the origin of longitudes in all future maps and hydrographic charts. The gain in simplicity and convenience will be immense.

Let us hope that England will respond to the international compliment thus paid to her by the adoption of the metric system of weights and measures.

Resolutions and Recommendations adopted by the Conference.

The conference strongly recommends that:—

(1) In all ephemerides the ecliptic coordinates of the sun should be given for Greenwich mean noon, and that the equatorial rectangular coordinates should be given for midday and midnight of Greenwich mean time.

(2) The ecliptic coordinates of the moon should be given at least for 0h. and 12h. of Greenwich mean time.

(3) The ecliptic heliocentric and geocentric coordinates of the planets should be given for 0h. or 12h. of Greenwich mean time.

(4) The ephemerides of the stars, that is to say, their correction from mean to apparent place, should be calculated for upper transit at the meridian of Greenwich.

The conference is of opinion that the adoption of the meridian of Greenwich for all ephemerides should be realised as soon as possible.

The conference is of opinion that in all catalogues and all collections of observations declinations instead of polar distances should be adopted.

The conference decides that those portions of the ephemerides which deal with the data necessary for the calculation of the perturbations of the small planets and comets shall be based on the masses of the planets adopted by Newcomb.

The conference decides that the names of stars shall be accompanied by a letter indicating their spectral type in terms of Pickering's notation. It is of opinion that these indications (so far as they have been determined) should in future be given in the list of 3064 stars to be published by the Bureau des Longitudes.

The conference decides that in future the stars in the fundamental and standard lists of Auwers, Boss, and Newcomb shall be designated by the letters A, B, N, and the Backlund-Hough stars by the letters BH.

For the prediction of occultations of stars the list of the Nautical Almanac shall be adopted.

The commission adopts the following resolutions:—

For the sake of uniformity in the calculation of parallaxes, eclipses, and occultations, the ephemerides shall adopt for the value of the compression of the earth the number 1/297·0, resulting from the final researches of Messrs. Tittmann, Hayford, and Helmert.

For like reasons, in the calculation of eclipses, the semi-diameter of the sun (Auwers) shall be retained, as already employed in all ephemerides.

The bureaux charged with the calculation of eclipses of the sun and moon and the occultations of stars shall choose in common agreement the tables and apparent diameters which they find most desirable, taking care to communicate in the most precise and complete fashion the data which they employ and the origin whence the adopted data have been derived.

The conference decides that the Connaissance des Temps shall continue to calculate the positions of the sun and of the planets from the Leverrier-Gaillot tables, but that bureau will in future compute the positions of the moon from the new tables of M. Radau, which are based upon Delaunay's theory. In the other ephemerides these calculations shall be based on the tables of Newcomb and of Hill for the sun and planets, and on Hansen's tables, with Newcomb's corrections, for the moon until such time as the latter tables shall be replaced by the new tables of Brown.

This second series of solar, planetary, and lunar calculations shall be undertaken by the Nautical Almanac Office, with the exception of the ephemeris of Mercury, for which the office of the "Berliner Jahrbuch" shall be responsible.

Relative to the Stars.

(1) The corrections from mean to apparent place of the stars BH shall be computed at the National Almanac Office, and be printed by the Observatory of Pulkowa; the same will apply to the daily corrections of the principal fundamental clock-stars, which latter shall include the lunar terms of short period.

(2) The ephemerides of such of the stars A, B, N as do not occur in the list of Auwers stars, which is published annually in the "Berliner Jahrbuch," shall be calculated and printed in the observatory at Turin.

(3) The ephemerides of the Auwers stars shall be calculated and printed by the "Berliner Jahrbuch," with the exception of the 343 stars printed within brackets; the calculation of the ephemerides of these latter shall be undertaken by L'Almanaque Nautico.

(4) The ephemerides of the pole-stars, that is to say, of all the stars situated within 10 degrees of north or south polar distance which are to be found in the provisional list of 3064 stars published by the Bureau des Longitudes, and of the other polar stars hitherto given in the ephemerides, shall be calculated from day to day by the Bureau des Longitudes, and shall contain the terms of short period, the values of which shall be separately indicated, however; for polar stars situated between 80° and 83° declination it will be sufficient to give the ephemerides for each alternate day.

The Connaissance des Temps undertakes to print all the ephemerides of the above-mentioned stars which are not given in other similar works.

The ordinary ephemerides of the stars shall be calculated to 0·001s. in R.A. so far as 60° of declination and 0·01″ in declination, not for each tenth day, but for each tenth successive culmination at the meridian of Greenwich in order to facilitate interpolation; they will be accompanied with the data necessary for the computation of the terms of short period.

The calculation of the constants of reduction shall be carried out by each bureau in their usual way with four or five decimals.

Relative to Eclipses and Occultations.

The calculation of eclipses of the sun and moon shall be made (in conformity with the rules established by the preceding resolutions) once by the American ephemeris and once by the Connaissance des Temps.

The computation of occultations shall be made in duplicate by the American ephemeris.

The predictions of eclipses and the elements of occultations shall be calculated with all possible precision.

Relative to Satellites.

(1) The calculation of new ephemerides of the four principal satellites of Jupiter and their phenomena shall be made by the Bureau des Longitudes, and be based on Sampson's new tables.

(2) The ephemerides relative to the ring and to the satellites of Saturn (with the exception of Phœbe) shall be calculated by the "Berliner Jahrbuch."

(3) The calculations of the ephemerides of the satellites of Mars, of the new satellites of Jupiter, of Phœbe, and of the satellites of Uranus and Neptune shall be made by the American ephemeris.

The ephemerides relative to physical observations of the sun, moon, planets, &c., shall be calculated by the American ephemeris, except the ephemeris of the crater Mösting A, which will continue to be published by the "Berliner Jahrbuch."

The computation and printing of the ephemerides of the small planets and variable stars shall be undertaken by the "Berliner Jahrbuch."

It is desirable that the calculations made by any one of the bureaux should be communicated to other bureaux, which have to use them at least three years in advance.

The above conventions will be put in force in such a way as to be complete in 1917.

It is understood that the above arrangements are provisional, subject to approval by the Governments concerned.

THE SOLAR PHYSICS OBSERVATORY.

WE take the following from Wednesday's *Times* (November 29):—

At the Congregation on Thursday, December 7, the following Graces will be offered to the Senate:—"That the recommendations contained in the report, dated November 13, 1911, of the Council of the Senate on the proposed transference of the Solar Physics Observatory to Cambridge—namely, (1) that the University accept the charge of the Solar Physics Observatory, subject to the conditions laid down in the letter from the President of the Board of Education; (2) that steps be taken to obtain the powers requisite for the suspension of the election to the Plumian professorship of astronomy and experimental philosophy when it next becomes vacant, for a time sufficient to enable the University, if necessary, to obtain changes in the statutes which define the title of the professorship and the duties of the professor—be approved."

The proposal to transfer the Solar Physics Observatory to Cambridge was discussed in the Senate last Thursday. The proposal was warmly welcomed by Prof. Newall, Prof. Sir George Darwin, Prof. Sir Robert Ball, and Dr. Glaisher. The arrangements for organising the work of the department and for the provision of the necessary site were fully explained.

Nothing seems to have been said about the financial arrangements necessary to secure permanence. In the report of the so-called Departmental Committee the following passage occurs:—

With a view to securing the permanence of any arrangement that may now be made, the committee desire to point out the importance of attaching the directorship of the Solar Observatory, if established at Cambridge, to a professorship which is not merely of a temporary character. The University may not be in a position, at present, to give any definite assurance that the professorship will be renewed at the expiration of the present tenure; but we consider it highly desirable that the Government should ascertain, before coming to a final decision, whether the University is willing at an early opportunity to consider favourably the establishment of a professorship of astrophysics on a permanent foundation.

The "permanence" contemplated by the Council of the Senate only becomes operative on the death or resignation of the present Plumian professor. It is taken for granted that the unpaid professorship of astrophysics will not be vacated for any cause in the interval. What is to happen during a vacancy is not stated. Is this the kind of "permanence" contemplated by the Government? Is the next vacation of the Plumian professorship, which everybody hopes will not occur for many years, the "early opportunity" referred to in the report of the committee?

NOTES.

FOLLOWING on the announcement last week of the appointment of an expert committee of investigation into the etiology, &c., of foot-and-mouth disease comes the interesting and, if it should be confirmed, important announcement of the discovery of the causal organism of this serious animal scourge. This claim has been put forward by a German bacteriologist, Dr. Siegel, in a paper read at the annual Congress of Prussian Veterinary Surgeons in Berlin. Dr. Siegel claims to have found the organism in the blood stream and in the local lesions in affected animals, to have cultivated it in artificial media, and that in experimenting with his organism it has satisfied the postulates of Koch. Moreover, he claims to be able to produce some degree of immunity to the disease. Details of this interesting paper are not yet to hand; and in the meantime the claim must be accepted with the reserve which must obviously be accorded to the statement of the discovery of an organism that has up to the present eluded vigorous and systematic research by other experts of almost all nationalities. In the meantime, the full details of experiments will be anxiously awaited; and if they warrant it, it will be one of the first duties of the British expert committee to investigate them carefully, and either to confirm or refute the claims of Dr. Siegel. Should the discovery be confirmed, it will indeed be an enormous boon to the whole agricultural world.

THE Bradshaw lecture is to be delivered at the Royal College of Surgeons on December 6 by Mr. R. Clement Lucas, who has chosen for his subject "Some Points in Heredity."

THE Paris correspondent of *The Times* reports that Prince Roland Bonaparte has placed at the disposal of the French Academy of Sciences a sum of 10,000*l.*, which is to serve as a fund in aid of those of its members who are engaged in research work.

THE superintendent of the Indian Museum informs us that Mr. J. Coggin Brown, curator of the museum of the Geological Survey of India, accompanies the Abor expedition as geologist. The botanical work is in the hands of Mr. I. H. Burkill, reporter on economic products to the Government of India, while Mr. Stanley Kemp, assistant superintendent in the Indian Museum, is in charge of both zoology and anthropology, with Mr. R. Hodgart as taxidermist and assistant.

THE ringing of birds in order to study their movements has been referred to frequently in these columns. About twenty thousand birds have been ringed by correspondents of *British Birds*, the rings bearing the name of the editor of that journal, Mr. Witherby. One of these birds, a sea snipe, or redshank, was shot recently at Wesport, County Mayo, and it was assumed to be a bird escaped from captivity in London. A report in *The Times* of November 29 says:—"The incident has caused much local interest, since nobody in Connaught has ever heard of a tame redshank. It has among seabirds the reputation of being remarkably shy." Local opinion in Connaught as to the difficulty of taming a redshank need not be disturbed. The bird referred to was probably ringed by one of Mr. Witherby's correspondents far away from London, and it is unlikely that it was ever in a cage.

LIEUT.-COLONEL EDGAR A. MEARNS, U.S.A., retired, associate zoologist of the United States National Museum, who accompanied the Smithsonian Expedition to Africa, under the direction of Colonel Theo. Roosevelt, will be attached as naturalist to the Childs Frick Abyssinian Expedition, which will sail from London shortly to make natural history collections in the Abyssinian region. It is proposed to make as complete a collection of the animals of the Abyssinian region as possible. The journey will be primarily through Abyssinia, but will extend into British East Africa as well, and cover a portion of that country north of the field gone over by Colonel Roosevelt in 1909–10. One of the most important regions to be visited is in the neighbourhood of Lake Rudolf, and along the shores of the lake itself. It is expected that the opera-

tions of the expedition will cover a period of approximately seven months. There is no question that, even with moderate success, the United States national collections will be enriched by valuable specimens.

THE annual Huxley memorial lecture in connection with the Royal Anthropological Institute was delivered by Prof. F. von Luschan on November 23. Prof. von Luschan in his address said that to study the old ethnic elements of Western Asia it seemed best first to eliminate the more recent immigrations of Albanians, Circassians, Bulgarians, Franks, and Levantines. It is easy also to eliminate the different nomadic tribes, of which the Kurds are of special importance, being originally xanthochroic, with light hair and light eyes, whilst in all the other groups dark complexion is far predominant. The final result of anthropometric investigations—about 5000 men were measured—is that all Western Asia was originally inhabited by a homogeneous melanochroic race with extremely short and high heads, and with a "Hittite" nose. About 4000 B.C. began a Semitic invasion from the south-east, probably from Arabia, and by people looking like modern Bedouins. Two thousand years later begins a second invasion, this time from the north-west, and by xanthochroous, long-headed tribes, like the modern Kurds, perhaps half savage, and in some way or other connected with the historic Harri, Amorites, and Tamehu. The modern Turks, Greeks, and Jews are all three equally built up upon these three elements—the Hittite, the Semitic, and the xanthochroous Nordic. Quite differently is it with the Armenians and the Persians, who, and still more the Druses, the Maronites, and the smaller sectarian groups of Syria and Asia Minor, represent the old Hittite element, and are little or not at all influenced by the somatic character of alien invaders.

AN extra meeting of the Chemical Society was held at Burlington House on Thursday last, November 23, when Prof. Harold B. Dixon, F.R.S., past-president, delivered a memorial lecture in honour of Pierre Eugène Marcelin Berthelot. Prof. Dixon dealt fully with the life and character of Berthelot, referring to his persistence, his feverish energy, and devotion to his work. Berthelot, a native of Paris, was born on October 25, 1827, in a flat overlooking the Rue du Mouton. From this flat he must often have been a spectator of many violent scenes enacted during the revolutions of 1830 and 1848. He was educated at the Lycée Henri IV, and in 1861 was promoted to the chair of organic chemistry at the Collège de France, a position he held until his death. Reference was made to the intimate and enduring friendship between Berthelot and Renan, to Berthelot's romantic marriage with Madame Breguet, and to the great happiness of their married life. Berthelot was in Paris in 1870 during the Siege of Paris, and gave considerable assistance to his country in the manufacture of explosives. Madame Berthelot, with her children, had to leave her husband, going first to Rouen and thence to London. In addition to his professorial duties, Berthelot took his share in the government of his country. In 1881 he was elected a Senator, and five years later became the Minister of Education. In 1895 he held for a short time the position of Foreign Minister in the Bourgeois Cabinet. From 1863 onwards honour upon honour was bestowed upon him. He became a foreign member of numerous scientific societies, including the Royal and the Chemical Societies; and in 1900 he was elected one of the forty of the Académie Française. A year later, on November 24, 1901, the savants from the universities and societies all over the world met at the Sorbonne, in Paris, to celebrate the seventy-fifth anniversary of his birthday, the President of the French Republic (M. Loubet) presiding. In 1907 came the dramatic end to his illustrious career, he and Madame Berthelot dying together on March 18. Prof. Dixon dwelt at some length on the varied researches for which Berthelot was famous, referring more particularly to his work on the alcohols, and to his investigations on the acetylides of silver and copper and to his researches on explosions.

IN *Man* for November Messrs. J. L. Todd and G. B. Wolbach describe a series of stone circles in the Gambia. The type is in many respects analogous to those of Europe, and their object, judging from the remains discovered in the course of the excavations, was sepulchral. The Mandingo, who now occupy the region in which they are found, know little about them, and refer them vaguely to some tribe which preceded them. Their builders must have possessed more knowledge of stone-working than the Mandingos of the present day, and had considerable aptitude in lifting heavy weights. If the recent speculations of Prof. Elliot Smith be accepted, though they involve serious difficulties, the inspiration for the construction of these monuments came from the Egyptian stone-workers. The present Mandingos so far venerate these circles that they make war sacrifices near, or on, one of the stones, and bury spear-heads there. The excavations disclosed remains of weapons very like those used by the tribe at present. The facts, so far as they go, indicate that they were the work of a branch of the Mediterranean race, to which similar constructions in western Europe have, with some degree of plausibility, been attributed.

IN the first part of the Journal of the Royal Anthropological Institute for the current year Dr. H. J. Dunkinfield Astley discusses the well-worn subject of the origin and interpretation of the cup and ring markings which appear on stone monuments. Dismissing the numerous theories of previous inquirers, he suggests that they constitute the "heraldry of primitive man," being used, like the Churinga of the Australian Arunta, to define the exogamous groups. Before this explanation can be accepted more than one difficulty must be cleared up. We must be certain, in the first place, that the social organisation of the Arunta at the present day is comparable with that of the people who engraved these symbols on the monuments. Secondly, Dr. Frazer finds no proof of totemism or totemic clans in the races of western Europe, and it is unsatisfactory to assume that totemism is established by the existence of these symbols. Dr. Astley's paper is learned and interesting, but we fear that the secret of these markings must still remain a mystery.

IN her lecture "On the Marriage of First Cousins" (Eugenics Laboratory Lecture Series, No. iv.; London: Dulau and Co., 1911, pp. 39, price 1s. net), Miss E. M. Elderton presents the evidence for and against this type of matrimonial alliance in a clear and interesting manner. Consanguineous marriages have been objected to, and are objected to, on the ground that they result in (1) marked decrease in fertility; (2) high infantile mortality; (3) the occurrence of deaf-mutism, insanity, albinism, hare-lip, and other deformities with greater frequency among the offspring than among the general population. The conclusions arrived at may be broadly stated as follows:—(1) there is no evidence available to indicate whether the marriages of first cousins are more often absolutely sterile than those of persons unrelated to one another, but, omitting sterile marriages, the average number of children is approximately the same in both cases; (2) the statistics collected by Mr. Arner in America, and published in the year 1908, tend to

show that among the issue of consanguineous marriages the death-rate of persons under twenty years old is considerably higher than the normal; (3) the evidence that the marriage of cousins is more likely to lead to albinism, deaf-mutism, and insanity among the offspring appears to be conclusive.

In No. 42 of Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India, Major Rost and Captain Williams contribute the results of their own researches to the much discussed question of the cultivation of the leprosy bacillus. Although this organism has long been known and seen in the tissues of lepers, all attempts to grow it had until recently proved unsuccessful; and even now considerable scepticism is felt as to the identity of the bacteria isolated with the actual causal agent of the disease. The authors describe the organism which they obtained from cases of leprosy, and the effect produced on patients by vaccines prepared from it. In No. 41 of the same Scientific Memoirs Captain MacGilchrist considers, as the basis of original experimental work, the suitability of different preparations of quinine in medical practice. Attention is paid, in the main, to the solubility and absorbability of the different salts, and the various modes of administering them.

The thirtieth Bulletin of the Sleeping Sickness Bureau contains an account of the intracellular phase of the rat-trypanosome, *Trypanosoma lewisi*, in its development in the rat-flea, recently discovered by Minchin and Thomson. This phase was found in fleas from twelve to thirty-six hours after they had fed on the blood of an infected rat, and appears to represent the first stage in the developmental cycle of the trypanosome in the flea. The trypanosomes penetrate into epithelial cells of the flea's stomach, grow very large, and divide into a number of trypanosomes of normal size. The daughter trypanosomes are usually eight in number. They are formed by division of the parent body within its own periplast; the flagellum of the parent is retained and moves actively until nearly the last moment, when it disappears, and the body becomes spherical and tense, and bursts suddenly, setting free the daughter trypanosomes in the cytoplasm of the host-cell, whence they find their way out singly into the lumen of the stomach.

Certain small aurochs' skulls from the diluvial deposits of Belgium are described by Mr. R. v. d. Malsburg as a so-called new species, under the name of *Bos* (*urus*) *minutus*, in Bull. Internat. Ac. Cracovie, 1911, No. 5. Unless, however, the term *urus* be used in a generic sense, it would seem that a subspecies is intended. Under various forms, the author considers this *Bos minutus* to be the connecting link between the typical aurochs (which is regarded as the descendant of the Indian *B. namadicus*) and modern cattle.

We have to acknowledge the receipt of a copy of a catalogue of the exhibits in the British section of the International Shooting and Field Sports Exhibition, held at Vienna last year. The British section, it will be remembered, was in the hands of the Government, and the catalogue is therefore issued—after the usual delay—by the official publisher. The book is well got up and well illustrated, and the section on big game—which forms the bulk—will possess a permanent value as the first attempt (unfortunately incomplete) at a list of the big-game fauna of the British Empire.

In the Annals of the Transvaal Museum for July, 1911, Mr. J. Hewitt produces evidence to show that the maxillary bone of the viperine skull is more probably derived from the corresponding element of the proteroglyphous than of the opisthoglyphous section of colubrine snakes; in other words, that the Proteroglypha, rather than the Opisthoglypha (to which that position is assigned in the British Museum Catalogue of Snakes), have the stronger claim to be regarded as the ancestral stock of the vipers. The evidence derived from snake-venom seems to lend support to this view. In a second article (in Dutch), Dr. E. C. N. Hoepen describes a new generic and specific type of stegocephalian from the presumably Permian strata of Senekal, Orange River Colony, under the name of *Myriodon senekalensis*.

To *Naturwissenschaftliche Wochenschrift* for November 5 Dr. Otto Wilckens contributes an article on the extinction of animal groups during geological history, in which special attention is directed to ammonites, dinosaurs, and trilobites. Whether these groups—like the ammonites at the close of the Cretaceous—became completely wiped out by some general cause (*e.g.* over-specialisation), or whether, as Dr. Steinmann believes, they developed into new forms, is a question which is argued at some length. In the case of the ammonites the author is apparently inclined to favour the view that they may have become modified into Argonauta and the other octopods, although he rejects Steinmann's theory that dinosaurs developed into great flightless birds, that were exterminated by men, or that the "enaliosaurians" gave rise to whales and dolphins and pterodactyles to bats.

To *The American Naturalist* for November Mr. H. A. Allard contributes the second part of his account of the behaviour of bees when visiting the blossoms of cotton-plants. These bees were, of course, usually in the habit of visiting the ordinary American cottons, the flowers of these being furnished with certain nectaries which are absent in Asiatic cottons. When the insects came to fields where American and Asiatic cottons were growing side by side, they visited both indiscriminately, but when they alighted on Asiatic flowers they quickly perceived their error, and departed. "These visits of the bees to the outer basal portion of the Asiatic cotton-blossoms indicate that the visual powers alone were employed throughout the process." On the other hand, it is considered probable that bees ascertain the whereabouts of cotton fields by their sense of smell, a large area of cotton in flower giving off a distinct odour on a fine day.

The Tertiary giraffes of India form the subject of a monograph by Mr. Guy Pilgrim, published in the *Palaeontologia Indica* (new series, vol. iv., No. 1). Years ago Mr. Lydekker, in face of the opposition of the late Prof. Rütimeyer, asserted that Sivatherium and its allies were undoubtedly giraffoids. Now that his views are definitely accepted, the list of Siwalik representatives of the group is a long one; and Mr. Pilgrim has done well in bringing the available information up to date. Following the modern fashion, he divides the Siwalik species into brachycephalic and dolichocephalic types; and he has likewise been enabled to throw considerable light on the respective geological horizons of the various forms. The most generalised Siwalik representatives of the group are described by the author under the name Progiraffa, but as one of them was, for a time, called Propalæomeryx by Mr. Lydekker, the latter designation is clearly entitled to stand. Whether it be in error or by design that some of the lower jaws are figured with the teeth pointing downwards, the effect is decidedly bad.

The identification of the mosses collected on the Scottish Antarctic expedition having been entrusted to M. Jules Cardot, his report, received in separate form, is published

in the Transactions of the Royal Society of Edinburgh (vol. xlviii., part i.). The chief collection, from Gough Island, yielded twenty-one species, of which eleven are endemic; the solitary bog moss, *Shagnum scotiae*, is a new species, but represented also on the island of Ascension. Only two of the species are recorded from Tristan d'Acunha, and, although more common species may be expected, the author finds a closer affinity with the moss vegetation of the Magellan region. The new species from Gough Island and Ascension are described and illustrated.

THE October number of *Tropical Life* contains instructive articles on various economic products. In connection with the cultivation of the coco-nut palm, attention is directed to the fine grade of coco-nuts shipped from San San Blas, on the Panama coast, to the New York market, and to a cultivator suitable for removing strong-growing weeds from plantations. A discussion of the value of Nipa palms for the production of sugar and alcohol is based on the recommendations of Dr. H. D. Gibbs, of Manila, who affirms that an area of 100 hectares would supply sufficient raw material to keep a sugar-mill in continuous operation. Statistics relative to soya-bean cultivation in Portuguese East Africa are quoted, according to which a harvest varying from 25 to 40 bushels of seed per acre is obtainable; the yield of oil averages about 17 per cent. of the seed.

A *résumé* of recent researches into the nature of "graft-hybrids," culminating in the periclinal and sectorial chimæras obtained by Prof. H. Winkler and E. Heuer, is contributed by Dr. H. Fischer to *Naturwissenschaftliche Wochenschrift* (September 24). A description is given of the five composite types produced from grafts of the tomato and common nightshade by making an incision and so developing a new shoot from the point of union of scion and stock; and an illustration is supplied of the most complex combination, where the different branches represent the species *nigrum*, *Lycopersicum*, *Koelreuterianum*, *Gaertnerianum*, and *tubingense*. It is also explained how the solution was evolved by Dr. E. Baur from a study of the arrangement of coloured and colourless areas in the leaves of zonal pelargoniums. In both phenomena there is a mere juxtaposition of tissues derived from two original types, so that the term "graft-hybrid" proves to be a misnomer, and chimæra is accurately applied.

PROF. TITO ALIPPI has recently made a further contribution to our knowledge of the mysterious sounds known in different parts of the world as mist-poeffeurs, marinas, Barisâl guns, &c., and for which he proposes the name of *brontides* (*Boll. della Soc. Sismol. Ital.*, vol. xv., pp. 65–77). The new observations which he has collected come chiefly from the district surrounding Urbino and Rimini, in the north-east of Italy. The phenomena observed in this district follow the same laws as in other parts of Italy. They are well known in some localities and almost unknown in others not far distant. The detonations are usually described as resembling peals of thunder. They are heard most frequently in summer, with a clear sky and calm air, and generally occur in groups, and seem to come from the south-west. They do not appear to have any relation with local earthquakes, and are generally regarded by their observers as presaging bad weather, and especially snow in winter. From inquiries made elsewhere, Prof. Alippi concludes that brontides are practically absent from Sardinia and are almost quite unknown in all the western Alps.

So long as the bench-marks of the levelling system of this country are indicated by so crude a mark as the broad-arrow chiselled in masonry, or even cut upon wood, they do not respond to the needs of modern precise levelling, and small changes in such marks are not to be accurately determined. But in view of the probable relevelling of the main lines, and the employment of hemispherical-headed bolts for the principal points, the experience of the stability of bench-marks at Hamburg is of interest. There during the last twenty-five years the precise levelling has been checked from time to time, and a record of the changes in level of bench-marks has been kept, the results of which are given in the *Zeitschrift für Vermessungswesen* of March 11. The bench-marks are partly on high, dry ground, and partly on moist ground which is more or less affected by the rise and fall of the tide; they are also classed as on buildings, on bridges, walls, and such masonry constructions, or on stone pillars founded on a concrete block. Of the 315 marks on the dry ground, of which 301 were on buildings, 76 have shown no settlement in twenty-five years, 118 have settled from 1 to 5 mm., 68 from 6 to 10 mm., and 53 from 1 to 4 cm. In moist ground, where 399 out of 552 marks were on buildings, 291 had settled more than 1 cm., the maximum case being 21 cm.; and of these 243 were on buildings, so that under such conditions marks on separate masonry pillars or small masonry works were less affected.

THE U.S. Weather Bureau has sent us copies of its meteorological charts of the great oceans for December. In addition to the usual data which occupy the face of the charts, the reverse sides include articles on the average air and sea temperatures for that month, illustrated by special charts. Prof. McAdie supplies some interesting details relating to the steps taken for obtaining wireless telegrams from vessels in the North Pacific, and for supplying vessels with a synopsis of weather conditions and forecasts. Cablegrams are received from Honolulu, Manila, Shanghai, and Nemuro (Japan), and, through the courtesy of the "Western Wireless Press Association," wireless messages will be sent broadcast from San Francisco daily for the benefit of vessels on the Pacific. Thus what has been accomplished on the Atlantic, as regards radio-telegraphy, seems likely to be realised shortly on the Pacific also.

AN important investigation by Dr. Hugo Karsten relating to the state of the ice in the Gulf of Finland and the northern part of the Baltic forms the sixth part of *Finnländische hydrographisch-biologische Untersuchungen*. It comprises observations made during the winters of 1897–1902, with ice-charts for each year, showing by different tints the conditions at three or four different times during the season. The state of the ice naturally differs considerably in time and space in different years, but at present there is no general and theoretical discussion of the data. This is promised with the next volume, which is to appear shortly, and will, we feel sure, be a very useful addition to our knowledge of oceanography.

IN further support of his theory of the existence in the electric discharge through vacuum tubes of "magnetic rays" made up of doublets formed by the combination of a negative electron with a positive ion, Prof. Righi describes two new experiments in the *Rendiconti* of the Academy Lincei, part iv., and in *Le Radium* for October. The first consists in bringing a bulb, in which an electrodeless discharge is being produced by an oscillating discharge through a flat coil outside it, into the magnetic field of a coil through which a direct current is flowing. The luminous ring stretches out towards the coil and becomes bell-shaped. In the second experiment canal rays are produced behind a kathode of considerable thickness placed obliquely to the axis of the tube and pierced by a small

hole at right angles to its surfaces. The canal rays are received on a plate which is connected to a galvanometer. When a magnetic field parallel to the axis of the tube is established, the "magnetic rays" produced fall on a second plate, which can also be connected to the galvanometer. This plate is found to receive no current whatever from the magnetic field, but the first plate receives a positive current, which decreases as the magnetic field increases.

IN laboratories remote from large towns, the absence of a gas supply is the cause of much difficulty; and this applies to chemical, physical, bacteriological, agricultural, and metallurgical laboratory work. Carburetted water gas has been used in some cases, but has been shown to be attended with some drawbacks. We have received a pamphlet from Messrs. Mansfield and Sons, of Birkenhead, describing their oil-gas apparatus for laboratories. For the gas plant great durability and simplicity is claimed. Any kind of oil (mineral, animal, or vegetable) can be used for cracking, and no skilled labour is necessary, since putting a shovelful of coal on the fire every twenty or thirty minutes, and seeing that the oil is flowing in, is all the attendance required. The oil gas produced is permanent, has a very high calorific value, and requires no purification before use. This gas can be used in ordinary burners and appliances for laboratory use, provided that the gas jet is reduced in size to correspond with the higher carbon contents of the gas. Particulars are given in the same list of Bunsen burners, furnaces, drying and sterilising ovens, blow-pipes, and water heaters modified to burn oil gas.

THE memorandum of the Manchester Steam Users' Association for the year 1910 contains some interesting investigations by their chief engineer, Mr. C. E. Stromeyer, on the trustworthiness of mild steel. Some of the results have been presented at the Iron and Steel Institute; and in the present paper Mr. Stromeyer gives subsequent data confirming the view that the presence of nitrogen gives a bad steel likely to crack in undergoing the necessary workshop processes or in subsequent working of the boiler of which it forms a part. The evidence points to the fact that steels in which the percentage of phosphorus added to five times the percentage of nitrogen exceeds 0·08 will be untrustworthy in working. The author has tried many mechanical tests with the view of discovering one which would differentiate between trustworthy and untrustworthy steels, but without success. Except as regards bad heat treatment, chemical determinations, more particularly of phosphorus and nitrogen, are the only available guides when the process of manufacture and the composition of the raw material are not known. Engineers, however, are not likely to place overmuch confidence in a test which they cannot check, and will prefer to continue to rely on the reputations of the manufacturers, combined with a few mechanical tests.

THE third part of the work known as "Harmsworth Popular Science," edited by Mr. Arthur Mee, which is appearing in fortnightly sevenpenny volumes, has been received. In it the story of the evolution of the earth as the abode of plant and mineral life, the appearance of man and his gradual development, and his subsequent conquest of nature and the organisation of human society, is continued in the same popular manner as in previous issues. The work is profusely and excellently illustrated, and the account it provides of the triumphs of science will serve to encourage among ordinary readers an appreciation of the extent to which human progress is indebted to the labours of men of science.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR DECEMBER:—

Dec. 3. 19h. 39m. Saturn in conjunction with the Moon (Saturn 4° 5′ S.).
4. 15h. 55m. Mars in conjunction with the Moon (Mars 0° 50′ S.).
6. 22h. 0m. Mercury in conjunction with Lambda Sagittarii (Mercury 0° 1′ S.).
7. 7h. 0m. Mercury at greatest elongation E. of the Sun.
10. 23h. 0m. Vesta in conjunction with the Moon (Vesta 0° 28′ S.).
15. 15h. 0m. Mercury stationary.
16. 2h. 58m. Venus in conjunction with the Moon (Venus 3° 39′ N.).
22. 10h. 54m. Sun enters sign of Capricorn. Solstice.
" 14h. 43m. Uranus in conjunction with the Moon (Uranus 4° 36′ N.).
25. 4h. 0m. Mercury in inferior conjunction with the Sun.
29. 9h. 0m. Mars stationary.
31. 3h. 59m. Saturn in conjunction with the Moon (Saturn 4° 1′ S.).
" 20h. 10m. Mars in conjunction with the Moon (Mars 0° 1′ S.).

OBSERVATIONS OF MARS.—Nos. 4537–8 of the *Astronomische Nachrichten* contain several important records of recent observations of Mars. Under date November 21 Prof. Lowell telegraphs: "First morning frost Mars observed since November 3, 30° from S. pole on sunrise limb."

M. Antoniadi reports an encroachment of Syrtis Major, since 1909, on the W.S.W. of Libya to the extent of about 100 km., and several other changes. The chief interest of the observations appears to be in the apparent variations wrought by changes in the Martian atmosphere. M. Antoniadi suggests that, with these eliminated, the actual changes in the majority of the small details of the planet's surface would be very few. The intrinsic colour of such "*îles*" as Argyre 1, Noachis and Hellas, it is deduced, is red, and their apparent bronze hues are produced by the passage of yellow cloud screens.

M. Comas Sola records observations made at the Fabra Observatory, Barcelona, during October 9–16. A new canal was seen on October 9 to the east of Syrtis Major; it appeared to correspond to a prolongation of Nubis, which, passing L. Mœris, extended as an arc towards Triton. The whole region of Isis and Libya was covered by an immense, oval, brilliant cloud on October 11, the new canal being completely hidden in parts; this veil afterwards moved away at about 30 km. per hour. M. Comas Sola tentatively suggests that volcanic action on Mars would account for the production of these massive veiling clouds.

Important changes are also reported by the Jarry-Desloges observatories at Massegros and Sétif. Nepenthes and Nilosyrtis are said to be enormous, and Ausonia and Hesperia greatly changed; early in November the diameter of the south polar spot was 1·2″.

ARE THE WHITE NEBULÆ GALAXIES?—This question is attacked from several directions by Prof. F. W. Very in No. 4536 of the *Astronomische Nachrichten*, and the discussion of the various points is exceedingly interesting. Considering the relative brightness of nebulæ of different diameters, he arrives, first, at the conclusion that the light from these extra-galactic bodies does suffer absorption in interstellar space, and therefore one of the great objections to an infinitely extended universe, the apparent darkness of the sky, is explained. Then the apparent sizes and brightnesses of these bodies are compared with those of other celestial bodies of which the distances are approximately known. This leads to results as to the intrinsic brightness of the white nebulæ, hence to the question of their star-density, and, finally, it is found that these celestial objects are probably galaxies. Their diameters appear to differ to at least a fourfold extent, and the dimensions and brightness of the component stars are closely allied to those obtaining in our own stellar system. Of course many assumptions are necessary in such a discussion; but it is

interesting to note that Prof. Very deduces for the chief object of this class, the Andromeda nebula, a distance of about 1600 light-years, and suggests that the faintest and smallest of the white nebulæ may represent galaxies at a distance of one million light-years.

METEOR STUDIES.—All meteor observers would find Dr. C. P. Olivier's thesis, based on the study of more than 6200 meteors, of great interest. The determination of orbits was the primary motive, and 175 parabolic orbits have been deduced; but the other results would probably interest the average observer more. For example, the orbit of Halley's comet and that deduced for the η Aquarids are so remarkably similar that identity of origin is assured. But the size of the meteoric current is shown to be enormous, and on May 12, 1910, it was 13 million miles' radius. The evidence for stationary radiants is shown to be very weak, and the existence of such phenomena is in doubt. A special study of the so-called α-β Perseids was made, and the result indicates that they exist only in August. Duration of visibility is connected with colour, yellow meteors having the shortest, red and orange longer, and white and green meteors the longest, periods of visibility. The paper is published as an extract from the Transactions of the American Philosophical Society, N.S., vol. xxii., part i.

POPULAR OBSERVATORIES.—From time to time we have in these columns welcomed the establishment of observatories, of which the chief aim is to popularise the science of astronomy. Unfortunately, it would appear that the desire and the means to organise such institutions are greater on the Continent than here. The latest addition to the list, established at Munich, is described in No. 2007 of *La Nature*, and from the excellent illustrations it is evident that this *observatoire populaire* is well equipped. At first the organisers planned to mount the instruments on a high tower, and thus to escape some of the astronomical disabilities of an urban site; but the Commission of Architecture, which looks after the artistic amenities of Munich, decided that this project would mar the town's beauties, so the astronomers have to put up with an observatory placed at a lower altitude.

THE GREEK QUESTION AT OXFORD.

ON Tuesday, November 28, the statute providing for the exemption of candidates in the honour schools of mathematics and natural science from the necessity of offering Greek in Responsions was submitted to Convocation and rejected by a large majority, the numbers being 360 for and 595 against. The question had been thoroughly discussed by means of letters to the Press and printed fly-sheets circulated more or less widely among members of Convocation. On one side it was alleged that the modicum of Greek required in Responsions, which is practically, though not statutably, an entrance examination to the University, could be of no service to anyone who did not follow the study further, and only acted as an obstacle in the way of matters more important for the end in view. On the other side it was maintained that even a moderate acquaintance with the Greek language and literature was of value to most men; and the authority of the late Lord Kelvin was invoked in support of the opinion that this applied with especial force to those engaged in the pursuit of natural science.

An argument that was used with some force by the opponents of the statute concerned itself with the effect likely to be produced by the passing of the present proposals, followed, as they no doubt would be, by further measures of a similar nature, upon the facilities for learning Greek afforded in the smaller schools. When Greek is once made optional at the older universities, it was said, a chief inducement for the maintaining of instruction in Greek will be removed, except in the case of the great public schools, the result of which will be that many boys well capable of turning a knowledge of Greek to good account will be deprived altogether of the opportunity of learning it.

There is no doubt whatever that some of the opposition to the statute was due to the fact that many of its supporters openly avowed that they regarded it as a mere temporary compromise, to be followed in due course by more stringent limitations on compulsory Greek. This deterred many who would have voted for the statute if it had been put forward and supported as a final settlement of the question. On the other hand it is at least highly probable that many supporters of the statute disliked its provisions, but voted for it because they knew that it would not dispose of existing difficulties, and that it might be replaced in course of time by something more to their mind.

Much interest was aroused over the question as to how far a body like Convocation, which is largely non-resident, could legitimately be appealed to against the decision of what was presumably a majority of resident teachers. On one hand it was held that Congregation, the members of which are resident and to a great extent engaged in the actual teaching and examining work of the University, must be best qualified to judge of the educational requirements of different classes of undergraduates. On the other hand it was pointed out that Convocation, consisting for the most part of men who after completing their university education had passed out into the world and joined the ranks of the various professions and public services, would be well qualified to estimate the value of the education which they themselves had received, and desired by them for their own sons. A matter of broad educational policy, it was maintained, might properly come within the purview of the latter body, while questions of detail should be left in the hands of the resident teachers. In addition to this it was pointed out that the majority by which the measure passed Congregation was very far indeed from being a majority of the whole body, less than half of the members of Congregation having actually recorded their votes on that occasion.

Notwithstanding the figures of last Tuesday's division, it would be a mistake to suppose that any considerable number of people are entirely satisfied with the present system of entrance examination. There is little doubt that the question of reform will again be mooted; and it may be hoped that some plan may be devised, perhaps on the lines of a "leaving certificate" to be gained at school, which will secure a reasonable amount of support from all parties.

PAPERS ON INVERTEBRATES.

AMONG a number of papers relating to invertebrates which have recently come to hand, the following are selected for notice:—

Bulletin No. 16 of the Connecticut Geological and Natural History Survey is devoted to the first two parts of a guide to the insects of that State, prepared under the direction of Dr. W. E. Britton. Part i., comprising a general introduction, is by the editor, while in the second part Mr. B. H. Walden treats the Euplexoptera and Orthoptera. Special attention is directed to the economic aspects of the subject.

The British spiders usually included in the heterogeneous group Tmeticus and certain allied genera form the subject of an article by the Rev. J. E. Hall in the third part of vol. iii. (new series)) of the Transactions of the Natural History Society of Northumberland, Durham, and Newcastle. It is now shown that the group is divisible into sections, one represented by Centromerus, in which there are only three outer falcal teeth, and the other by several genera (some of which are named for the first time) in which there are four or five of these teeth.

In a note on the Crustacea obtained during the trawling expedition fitted out by the New Zealand Government in 1907, Dr. C. Chilton (Records Canterbury Museum, vol. i., No. 3) states that the shell of a crab of the genus Paramithrax seems to be almost invariably infested by barnacles (*Balanus decorus*), which are in some cases so numerous and so large as to exceed the crab in bulk. A hermit-crab (*Eupagurus stewarti*) was found in some cases inhabiting a massive polyzoon apparently too big for the crab to move; in other cases it sheltered in straight tubes in a Millepora, these tubes, it is suggested, perhaps having been originally formed round sea-weeds, which subsequently rotted.

To the same author we are indebted for copies of two papers on local crustaceans, published in vol. xliii. of the Transactions of the New Zealand Institute. In the former of these Mr. Chilton revises the New Zealand representatives of the group (Stomatopoda) typified by the familiar European *Squilla mantis*, while in the second he catalogues the crustaceans at present known from the Kermadec Islands. Despite the fact that the crustacean fauna of those islands has been systematically collected, for the first time no new forms are recorded.

As the result of the examination of a collection of rotifers obtained from Clare Island, west coast of Ireland, Mr. C. F. Rousselet (Proc. R. Irish Acad., vol. xxxi., p. 50) finds that these organisms do not differ materially from those of the mainland.

On the other hand, in a paper on Irish annelids of the family Maldanidæ, Mr. I. Arwidsson (*ibid.*, vol. xxix., Sect. B, p. 209) finds himself in a position to name and describe two new species, one of which is also regarded as entitled to represent a new genus.

In Bulletin No. 71 of the U.S. National Museum is published the second part of Mr. J. A. Cushman's monograph of the Foraminifera of the North Pacific, this instalment being devoted to the primitive family Textulariidæ. Several new species and a few new genera are described. The group has been found to be of considerable interest from the distributional point of view. It is stated, for instance, that "many of the species occurring in the Indo-Pacific area extend southward to the region of Torres Strait. In the North Pacific, however, these species are, as a rule, confined to the western portion from southern Japan southward. The rediscovery of some of the species described by J. Brady, from almost the exact locality where they were dredged by the *Challenger*, is very interesting, and tends to show the restricted distribution of certain forms."

Rotifers of the bdelloid group indigenous to South Africa form the subject of an article, by Mr. J. Murray, in vol. iii., No. 1, of the Annals of the Transvaal Museum. Although the Central and North African representatives of the group had received some attention, very little was known with regard to those of the South, so that the author has been able to make considerable additions to our knowledge. The paper concludes with a summary of what is known with regard to African bdelloids generally.

In vol. viii., Nos. 4–6, of the University of California Zoological Papers Mr. C. A. Kofoid continues his account of the dinoflagellate animalcules of the San Diego area, dealing in the first two papers with the genus Gonyaulax and the morphology of its skeleton, while in the third (forming the fifth of the whole series) he describes, under the name of Spiraulax, a new generic type of the peridinid group.

The nine species of earwigs now found in the British Islands (some of which are introduced) form the subject of a coloured plate in the October number of *The Entomologist's Monthly Magazine*. According to Dr. M. Burr, nearly all these earwigs, with the exception of the common species, are rare and local. R. L.

LIPOIDS AND NUTRITION.

A WORD is perhaps necessary in explanation of the term lipoids. These are substances, contained in the outer protoplasmic layer of all cells, which resemble the fats in being soluble in organic solvents. They appear to be essential constituents, and are specially abundant in that tissue which pre-eminently manifests "vital properties," namely, the nervous tissues. The majority of them, though by no means all, contain both phosphorus and nitrogen. Very little is as yet known as to their constitution and properties.

At the present moment, when so much attention is being devoted to problems of nutrition, a communication by Prof. Stepp, of Giessen (in part v. of the *Zeitschrift für Biologie*), is of very considerable interest. The idea has been gaining ground that an ordinary diet contains certain constituents, present only in minimal quantity, the presence of which, in addition to the proper proportions of protein, carbohydrate and fat, is essential for growth and the maintenance of life. Experiments made with rice in connection with "beri-beri" have pointed to such a conclusion; and the work of Prof. F. G. Hopkins, of Cambridge, of which, so far, only a preliminary account has been given, has gone very much further in the same direction.

Prof. Stepp, who selected mice for his experiments, has studied the effect of extracting the food very completely with alcohol and ether before administration. The food used consisted of a dried mixture of rice, treated so as to be particularly rich in protein, and new milk; before extraction it was found to be a very satisfactory nutrient for mice. When fed, however, with the extracted food, the mice very soon died, showing that an essential constituent had been extracted from the food. The addition of mineral salts to the extracted food did not make it of any greater value, but the addition, on the other hand, of the evaporated extract enabled the mice to remain alive and thrive. Extraction in the manner described removes, amongst other things, fats from the diet. Accordingly, experiments were made in which butter or fats such as tripalmitin, tristearin, or triolein were added to the extracted food; in no case was the addition of the faintest value in preserving life. The essential substance is considered to be a lipoid which is absent from butter, though present in the milk plasma. In proof of this it is established that an extract of dried butter-milk when added to the extracted food is sufficient to keep the mice still in good condition at the end of six weeks. It is possible to measure the quantity of this lipoid required; and the experiments show that whereas the evaporated extract of 75 c.c. of milk per 100 grams of solid extracted food was insufficient, that from 200 c.c. of milk was more than enough to maintain health.

Certain of the lipoids have been isolated in a pure state, and their effect could be tested; it was proved that the addition of either lecithin or cholesterol to the diet was of no use. The essential substance is therefore of a very subtle character. Stepp's experiments with boiled milk are of some interest; though boiled milk by itself is of value to the animals, the alcoholic and ethereal extracts of it when added to the extracted food are unable to maintain life.

If these conclusions are substantiated, an altogether new trend will be given to work on nutrition.

WATER RESOURCES OF THE UNITED STATES.

OF the three volumes recently issued by the United States Geological Survey, that (No. 256) on "The Geology and Underground Waters of Southern Minnesota," by Messrs. Hall, Meinger and Fuller, is certainly the most interesting, and claims primary notice. It is a brochure of 406 pages, with a number of sections and diagrams and four folding maps, all descriptive of matters, physiographical, geological, and chemical, connected with water supplies in the southern two-fifths of the State of Minnesota—an area of 28,265 square miles, which is roughly about the size of Scotland or Ireland. The district contains two towns of importance, Minneapolis and St. Paul; but, apart therefrom, the whole, with its $1\frac{1}{4}$ million inhabitants, is essentially agricultural in character. The surface comprises three elevated plateaus of different levels, with trough-like depressions between, all, with the exception of the extreme south-east and south-west corners, composed of glacial drift deposited during the most recent ice invasion. "Nowhere is there a more typical example of a ground moraine left in the wake of a continental ice sheet than is exhibited by the extensive, slightly undulating, monotonous expanses of southern Minnesota, dotted with countless shallow lakes and ponds, and covered with an interminable network of swamps."

Generally speaking, the drift is yellowish at the surface to a depth of some 15 feet, where it changes to a dark colour, due, no doubt, to the presence of unoxidised iron; and the water contained in it is almost universally charged with that mineral in the soluble ferrous condition. The effect of this, and of other constituents, on the utility and value of the water for various purposes is discussed at some length, and the volume then proceeds to deal with

the subject of well-sinking, after which there is a useful series of analyses and particulars of the water obtainable in different localities.

Pamphlet No. 274, on "Some Stream Waters of the Western United States" (Herman Stabler), is almost purely statistical throughout, and gives analytical tables of the constituents of water taken from the basins of the Rivers Colorado, Columbia, Mississippi, Rio Grande, and Sacramento.

Pamphlet No. 265 deals with the "Surface Water Supply in the Basins of Hudson Bay and the Upper Mississippi." The observations are by Messrs. Follansbee, Horton and Bolster, and are akin to those already described in connection with others of the dozen districts into which the States have been mapped out for the purposes of hydrological investigation.

ROMAN SURVEYING.

IN the *Zeitschrift für Vermessungswesen* (Heft 21, 1911) Prof. E. Hammer discusses the precision with which the nations of antiquity were able to mark out lines on the surface of the earth with the means at their disposal. Taking, first, that portion of the frontier of the Roman Empire which existed as a straight line about 80 kilometres long from near the River Rems in Württemburg to the district of Wallfürn in Baden, he investigates the question whether this line was laid down approximately straight by chance, or whether it was intended to be a straight line and special care was taken to arrive at this result. Points on the line were located and their positions plotted on the cadastral maps (scale 1 : 2500), from which their coordinates were determined. From these the direction-angle of portions of the line was calculated, and also the mean departure of points on the boundary line from the true straight line. For a portion amounting to 29 km. of the whole length, the mean error in position of a point on the boundary was found to be ± 2 metres, which indicates a surprising accuracy in carrying such a line over rough ground, while for portions of it an even greater precision was attained. Further observations by Prof. Leonhard, not yet published, on the remaining 50 kilometres of the boundary indicate that the accuracy is there maintained. The Romans must have fixed a few principal points in prominent positions by signals at night, and then interpolated intermediate points; the observed accuracy could never have been attained by prolonging a line.

A second case is that of the amphitheatre at Pola, laid out by a Roman architect or land surveyor, which has been recently studied by an Austrian surveyor, Herr Hofrath A. Broch. Using a plan on a scale of 1 : 250, he investigated the accuracy with which the form of the amphitheatre as constructed approached an ellipse. Taking twelve points on the curve, their mean error in position from a true ellipse was but 15 cm., in spite of the weathered surfaces of the stone contributing to this uncertainty. The axes of this ellipse were $2a = 129 \cdot 9$ m. and $2b = 102 \cdot 6$ m., or in the ratio of very nearly 9 : 7, as in the case of many Roman amphitheatres. Prof. Hammer goes on to refer to the results obtainable in a similar way from stone circles, where it is important to determine not only their dimensions, but also their accuracy of construction. The accuracy attained at Stonehenge is referred to; and in mentioning the "Standing Stones of Stenness" he suggests that in the circle of 340 feet in diameter, formed of about 60 stones $17\frac{2}{3}$ feet apart, we may have had a circle of 60 stones exactly $(60 \times 17\frac{2}{3} = 1060)$ indicating a sexagesimal division of the circle.

THE NATURAL HISTORY OF TYNESIDE.[1]

AMONG the natural history societies of this country that of Tyneside stands out by reason of its illustrious traditions and successful enterprise. Without municipal assistance it has originated and maintained for many years a museum of high standing, and its members have contributed classical memoirs on the geology, flora, and fauna of Great Britain. The names of William Hutton, of the two Hancocks, of Joshua Alder, and of Hewitson, to mention only a few, are associated with some most careful and beautifully illustrated work. It is therefore fitting that an account of these men and of other single-minded devoted students of natural history who have worked on Tyneside should be commemorated in these Transactions as has been done in an article by Mr. Leonard Gill, the curator of the Hancock Museum. This article is the one of most general interest in the volume before us; but there are also other papers of more than local importance to which we may direct the attention of workers who are following similar lines of investigation.

The most important of these is the account of the Crustacea of Northumberland and Durham by Canon Norman and Dr. G. S. Brady. This is the most complete of any county list for this class, since the fresh-water and terrestrial forms are included in an exhaustive study that has occupied almost the lifetime of these distinguished carcinologists. Scattered through these records of 644 species are many interesting remarks; for example, the prevalence during the winter of Arctic Euphausiids, which are brought by a southward current so far down the east coast as Yorkshire: and the rediscovery of the Daphnid Leydigia, after a lapse of twenty years, in remarkable circumstances. In spite of the length of this list, two forms that might be expected to occur are not mentioned. Neither Cheirocephalus nor any Phyllopod is recorded, and Leptodora, so common in Cumberland, is apparently absent from Northumberland and Durham.

Perhaps the chief feature of these Transactions is the amount of attention that has been given to the study of obscure or neglected groups of invertebrates. In this respect the papers by Mr. Bagnall are especially worthy of mention. This indefatigable naturalist has not only dealt with the Collembola, but also with two much neglected groups of myriapods, the Pauropoda and Symphyla, and with the little-known Thysanoptera, or thrips. These papers constitute a valuable addition to our knowledge of the British Cryptozoic fauna. The arachnids, again, are energetically and successfully studied by members of this society; and several papers by Dr. Rendall Jackson and the Rev. T. E. Hull constitute not only additions to our knowledge of this section of the British fauna, but to that of the order as a whole. The careful description of that very rare Coal-measure arachnid *Anthracosiro woodwardi*, Pocock, by Mr. Leonard Gill, is a comparative study of the specimens found near Newcastle and elsewhere. Lastly, Miss M. C. Lebour's papers on the trematodes of the coast constitute a further instalment of good work on a very little known group; and there are other papers on topographical geology which we have not room to discuss. The society is to be congratulated on such a substantial output of valuable scientific work. As a suggestion, may we point out the desirability of printing the author's name as a headline on the left-hand page of these memoirs in order to facilitate references?

CANCER RESEARCH.[1]

THE Fourth Scientific Report, apart from the introduction, is restricted to three papers. The first, on spontaneous cancer in mice, by Dr. Haaland, treats of a large number of additional spontaneous tumours of the mouse since the Third Scientific Report was prepared. These tumours consist of carcinomata and sarcomata occurring in a variety of sites other than the mamma, and are considered from clinical, pathological, histological, and experimental points of view. The animals in which they were found have been submitted to a number of experimental tests in order to elucidate the relation between a tumour and the animal in which it arises. The second paper, on cancerous ancestry and cancer in mice, by Dr. Murray, deals with breeding experiments bearing upon heredity, which have been in progress for some six years with mice of known ancestry, and from which a large number of the tumours and mice studied in the first paper have been obtained. The third paper, on the behaviour of tumour-cells during propagation, is a general survey of the

[1] From the introduction to the Fourth Scientific Report on the Investigations of the Imperial Cancer Research Fund. By Dr. E. F. Bashford. Pp. xxi+223. (London: Taylor and Francis, 1911.)

observations made on all the tumours observed or propagated in the laboratory during the past eight years, and of the bearing of their relative constancy and variability upon the nature of some forms of cancer.

All three papers are intimately interdependent as regards the material upon which they are based, and they overlap in so far as each treats more especially of particular problems not excluded from consideration in the other two. Thus, as in all previous reports, the effort is made to co-ordinate the features of cancer as it occurs naturally with its behaviour under experimental conditions.

New facts are brought forward in support of the view that a malignant new growth arises from local causes in a circumscribed area, and that the relation of each malignant new growth to the affected animal is an individual one, parallel to that obtaining between the organs of the body and the organism as a whole.

Precise evidence is advanced of the existence of hereditary predisposition to the development of spontaneous cancer. It is apparently of the nature of a predisposition of certain tissues to pass into cancerous proliferation, and is not effective by determining an increased suitability of the animals primarily affected for the growth of cancer as tested by transplantation.

Tumour-cells derived from a single primary growth are shown to be liable during extended propagation to variations such as are met with, either singly or in combination, in other primary growths. It is assumed that this demonstration permits of the inference that corresponding variations occurring in the course of the prolonged proliferation of normal cells under the influence of chronic irritation may be responsible for the development of some forms of cancer.

The relations between benign and malignant new growths, and of both to normal tissue, have been studied both histologically and experimentally on an extensive material. Among the large number of tumour-strains that have been propagated by *passage* from one batch of mice to another for extended periods, there are included several reproducing very closely the features of normal tissue, either as regards its histology or its limited[2] power of growth in any one animal after homologous transplantation. Some tumour-strains, while retaining almost perfect histological differentiation, grow progressively in any one animal; while others, notwithstanding that they are quite devoid of histological differentiation, possess only a limited power of growth in any one animal. The gaps between the structure of normal tissue and the least differentiated tumours, on the one hand, and between the growth of normal tissue, when transplanted, and that of even the most rapidly proliferating tumours on the other, have been filled in by a continuous series of tumour-strains. Some of these approximate to normal tissue both in respect of structure and of power of growth on transplantation, and experiment has brought out still more clearly the pure arbitrariness of the conception of a fundamental difference between benign and malignant new growths.

The demonstration that cancer occurred in practically all races of mankind and throughout the vertebrates even when living in a state of nature, together with the demonstration of the only manner in which cancer can be transferred from one individual to another of the same species, viz. by implanting living cells, proved that it was not due to a common causal parasite. The wide zoological distribution of the disease, down to marine fishes, showed that it was not a recent acquirement such as might be referred to influences dependent on man's particular forms of civilisation. As has been frequently pointed out, the age-incidence of cancer in man and animals is, in the absence of communicability, compatible only with the recognition of the intrinsic cellular nature of cancerous proliferation.

The parallel behaviour of normal and cancer tissue, both as regards the absence of continued growth and the nature of the cytotoxic reactions induced when cancer is transferred from one animal to another of a strange species, proved that cancer had all the properties distinguishing the normal tissues of one species from those of another species.

[2] In spite of being possessed of a power of only limited growth in any one animal, tumours can be maintained in extended propagation by suitably accelerating the rapidity of *passage*. This has not yet been accomplished in the case of normal tissues.

The fact that transplantable tumours grow in normal animals as well as they do in spontaneously affected animals is evidence that the latter do not present a soil for the growth of cancer substantially different from that presented by normal animals. When this fact is contrasted with the almost invariable success of reimplanting into the animal a portion of its own spontaneous tumour, and the almost invariable failure of implantation of any spontaneous tumour into other spontaneously affected animals, the conclusion is arrived at that each tumour is peculiarly and genetically related to the individual in which it arises.

This conclusion, drawn from studying the growth of tumours under the different conditions just enumerated, is supported by the results of elaborate experiments on inducing resistance or immunity to the inoculation of cancer-cells under these different conditions. The features of resistance bearing upon the nature of cancer are briefly as follows. Resistance is induced only by the living cells, either cancerous or normal, of the same species. Under similar conditions the cancerous cells and the normal cells of strange species are both devoid of the power to induce resistance. An animal's own tumour and its own normal tissue are devoid of this power, and the means which prevent the successful inoculation of the tumour of another individual do not prevent the successful inoculation of an animal's own tumour. Tumour-tissue usually induces resistance against itself quite as well as, and, with regard to the phenomenon of spontaneous healing, much more effectively than, any other tumour. Furthermore, animals which have proved resistant to the repeated inoculation of a tumour have subsequently developed spontaneous tumours showing progressive growth. Thus experimental inquiries into the production of growth by inoculation, on the one hand, and its prevention on the other, agree in demonstrating individual relations as obtaining between a tumour and the animal in which it arises. The individuality of tumour-cells will be referred to later.

The individuality of cancer, both as regards the organism attacked and the tumour, would thus appear to have been placed at last beyond all further doubt. Such a relationship has long been maintained in various forms on the basis of deductions drawn from histological examination of the tissues at the site of the primary lesion and from the nature of dissemination; but this interpretation of the findings has been as vehemently combated. The combination of the results arrived at by microscopical investigation and experimental study appears to complete the demonstration. A long step has thus been taken in defining the direction in which the future investigation of cancer is alone likely to be profitable.

The conclusions as to the individuality of cancer are supported also by most important new statistical information given in the last report of the Registrar-General.[3] The new tabulation of the data for the years 1901–9 for England and Wales has permitted of an analysis being made of the figures recording the increase of deaths attributed to cancer, which brings out the fact that the increase during this period is referable to certain anatomical regions and not to others. For the first time it is fully demonstrated that it is erroneous to make statements of a disquieting nature about the increase of cancer in general. The analysis also shows that the incidence is very unequally distributed among the several situations, indeed, that the whole curve of incidence may be different for different organs. A progressive increase up to the highest age-periods is characteristic of the face, lip, mouth, bladder, urethra, and breast only. The other organs show a distinct diminution in the highest age-periods; but it is not yet possible to determine whether this curve indicates a liability rising to a maximum and followed by a fall, or is merely the result of ascribing deaths to other causes in the case of cancer of internal organs in aged people. Sufficient has been said to indicate how important are the problems which are solved or revealed by the improvement in the details given in the national statistics.

The study of the occurrence of cancer in mankind, and in domesticated animals in widely separated parts of the globe, has shown that the practice of peculiar customs (involving

[3] Seventy-Second Annual Report of the Registrar General of Births, Deaths, and Marriages in England and Wales (1909). (His Majesty's Stationery Office, 1911.)

the application of chronic irritants to particular parts of the body) provokes the disease in situations and organs from which it is absent when these customs do not obtain. It is reasonable to suppose that the frequency of cancer would be diminished if such practices as the use of the Kangri in Kashmir, chewing betel-nut in India, and eating very hot rice in China were discontinued. It is also reasonable to assume that the introduction into England of these exotic customs would greatly increase the frequency of cancer in this country.

So definite is the evidence of the *mediate* causation of certain forms of cancer by chronic irritants that the possibility of variations in the cancer death-rate may be admitted as regards particular organs and regions of the body. The possibility of a variation of the main incidence of cancer in conformity with changes in certain customs may also be admitted.

That irritation is really an important causative factor of cancer is an assumption which at present is justifiable only for certain forms of cancer occurring in particular parts of the body. In view of these considerations, and also because of the results of experiment as recorded in this report, it appeared desirable to have data of the incidence of cancer in persons pursuing various occupations and having different habits of life. For the purposes of comparison it will be necessary to learn not only the incidence of cancer on particular sites liable to irritation, but also its incidence on all other sites, as well as the frequency of the other causes of death in the occupations considered.

Breeding experiments with mice of known ancestry have been in progress for many years, and have been alluded to on several previous occasions, but only now have the data become sufficiently numerous to permit of conclusions being drawn. All due precautions have been taken to avoid errors in the interpretation of the figures. The data show that heredity plays a part in affecting the liability of the mouse mamma to develop cancer. At all age-periods the disease is more frequent when the mother, or either grandmother, or all three, have died from cancer of this organ than in the group in which these ancestors were free from the disease.

Apart from its bearing upon heredity, the obtaining of such mice is most important for furthering the experimental investigation of the genesis, nature, and, should it be necessary, artificial production of cancer, and for attempting to define the reasons for its apparently greater frequency in some geographical areas than in others. It will be obvious that a large field of investigation has been opened up by the segregation of mice into two groups of different liability, and it should be possible to obtain groups of animals of a still higher and a still lower liability. While it is at present impossible to explain how the liability is transmitted, it can be averred with certainty that it does not consist in the inheritance of a soil more suitable for the growth of cancer in general. It can only be inferred with some probability, that it is a local or circumscribed tissue predisposition, in virtue of which the mammary tissue is prone to pass from mere proliferative reaction into continuous or cancerous proliferation. Further, hereditary predisposition is only one of the factors concerned, for it has been found that chronic inflammatory changes are remarkably frequent in the mammæ of female mice of the laboratory; and other factors still unrecognised may exist. There is a considerable body of evidence to show that the predisposition is not a general one affecting the whole body equally, but that the tendency transmitted affects mainly one organ system, so that groups of animals may ultimately be obtained in which different organ-systems will present a definite predisposition, the other organs of the body not being unduly liable to the development of the disease.

To guard against pessimistic conclusions, it is well to point out that the influence of heredity has only been demonstrated by studying stocks in which this factor has been concentrated by careful mating, and that the influence is mainly exerted in the immediate descendants. Such a concentration as can be attained in experimental animals can only occur in the human subject, by hazard, as a coincidence of considerable rarity; and it is probable that the influence of heredity in the general population is manifested as an average predisposition of low general intensity.

In all previous reports guarded reference has been made to the well-known association of chronic irritation and certain forms of cancer, and it has been pointed out that, in common with all external conditions, they can only have *mediate* relation to the occurrence of cancer, the essential preliminaries which lie between them and its inception being regarded, not as their specific reactions, but as manifestations of properties inherent in the cells. The employment of the term "mediate" when directing attention to the relationship is due to an effort to elucidate those forms of cancer with which irritation is most constantly associated, without considering other forms in which the particular irritants concerned do not play a part, and due to the fact, already frequently emphasised, that the irritants have nothing in common beyond the capacity to excite extended proliferation of tissues (chronic inflammation), and their association with cancer.

The varied investigations of the past nine years have added a knowledge of new forms of irritation. It has become more and more evident that irritation, effective in one case, may be, and often is, quite ineffective in another species of animal, or even in other individuals of the same species. The experiments recorded in this report throw light both on the nature of predisposition to cancer, as alluded to above, and also on the long recognised, but inexplicable, relation between chronic irritation and cancer.

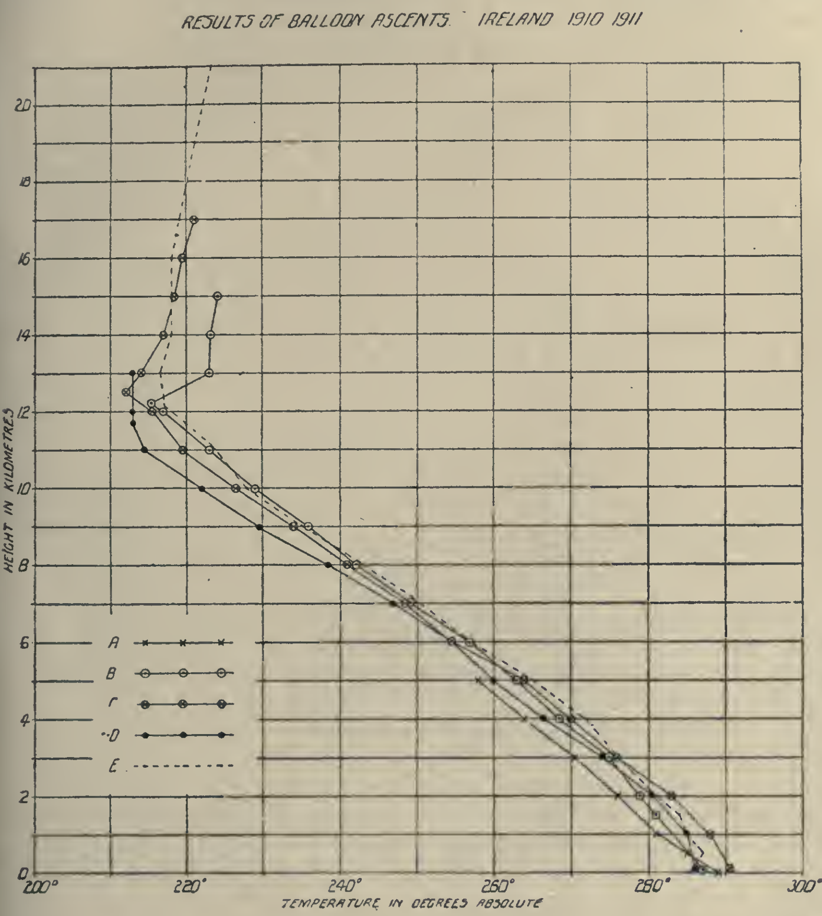
A closer definition of the nature of cancer will involve an analysis of the relation obtaining between the individual developing cancer and the tumour. This final analysis will be possible only on animals naturally afflicted with the disease, for, as pointed out consistently from the first annual report onwards, the genesis and the growth of cancer are distinct phenomena. The study of propagated cancer supplements its observation under natural conditions by investigation under varied artificial conditions, and has only an indirect bearing upon the genesis of the disease. Hence breeding experiments acquire enhanced significance, and are already being, and will continue to be, conducted on a much more extensive scale. An adequate supply of animals of differing liability to the disease must be made available for the elucidation of problems, some of which are already adumbrated; while past experience makes it likely that others, as yet unsuspected, will arise.

Because of the hope that they may ultimately have therapeutical bearings, another reference may be made to the induction of resistance to the inoculation of cancer and the means which modify the growth of transplanted tumours. Experiments along these lines bear at present upon the nature, but not upon the prevention, treatment, or cure of cancer; notwithstanding this fact the application of the results to the human subject has been urged in some quarters. In 1906–7 it was pointed out that a high degree of resistance to the transplantation of cancer did not exempt an animal from the spontaneous development of the disease. The importance of the observation was great; had immunity to the natural acquirement of cancer been also obtained, the control of the scourge would have been in sight.

In the Third Scientific Report the previous warning was re-enforced, and it was pointed out that none of the methods which had been found to influence transplanted cancer should be applied to man until they had been tested and found efficacious in the case of animals naturally affected. These warnings are borne out by further experience and inability, as yet, to modify the growth of cancer in the animal naturally affected. Instead of revealing analogies with infective diseases, and placing similar remedial and preventive measures in the hands of the physician and surgeon, the study of resistance to cancer has, until now, but brought investigators to the verge of a region filled with problems previously undreamt of. In the solution of these problems, or of more crucial ones not yet reached, lies the best hope of preventive and remedial measures; but the preliminary facts are so new to experimental biology, and as yet so imperfectly comprehended, that observers throughout the world are still engaged in discussing what may be their true significance as signposts indicating a road or roads by which the correct advance is to be made.

INVESTIGATION OF THE UPPER ATMOSPHERE.[1]

THE results of the observations at Barbados, referred to in last year's report, have been discussed by Mr. Cave in a paper read before the Royal Meteorological Society and published in its Quarterly Journal. A further supply of balloons and hydrogen has been sent to Prof. D'Albuquerque in order that he may continue the observations. Some difficulty has been experienced owing to the deterioration of rubber balloons in the climate of Barbados.



During the week August 7–13, 1910, for which international balloon ascents had been arranged over a large part of the northern hemisphere, arrangements similar to those described in last year's report were made for securing successful ascents in the British Isles, telegraphic forecasts being sent each day by the Meteorological Office to the observers. Altogether thirty-one balloons were liberated, of which nineteen were recovered and sixteen gave records of temperature to heights exceeding 10 km. Of the latter, five were sent up from Crinan, Scotland, five from Pyrton Hill, Oxfordshire, three from Manchester, two from Ditcham Park, Petersfield, and one from Oughterard, Ireland.

The British Association grant was allocated partly to ascents made by Captain Ley at Oughterard, latitude 53° 25′ N., longitude 9° 20′ W., in the west of Ireland, and partly to ascents made from Mungret College, Limerick. At Oughterard six registering balloons were sent up, and two of these were recovered. The results are shown in the diagram, A and B.

At the March meeting of the committee it was suggested that the authorities of Mungret College, Limerick, who had given evidence of keen interest in meteorological work, might be willing to liberate balloons during the international week. Such a course would avoid the recurrent expense involved in special journeys to Ireland for the ascents, and would permit of more frequent ascents being made. The college authorities expressed their willingness to fall in with the suggestion, and Mr. W. H. Dines undertook to provide instruments and balloons for preliminary ascents in connection with the short international series in June this year, and to send over someone to give necessary instructions in the preparation for the ascents.

Three balloons were liberated on this occasion, and two of them were recovered and gave records of temperature, in one case up to 17 km. The results are shown in the diagram. C, D. A balloon was also liberated from Mungret College in July, and the result is shown under E.

At the request of the joint committee, the International Commission courteously postponed the week for international ascents this year from September 4–9 to September 11–16, in order to permit of those taking part in the ascents attending the meeting of the association at Portsmouth. Arrangements have been made for further ascents from Mungret College during that week. (Since this report

Results obtained from Ascents of Registering Balloons in Ireland.

	AUGUST, 1910		JUNE, 1911		JULY, 1911
	A Oughterard, August 8, 8.10 p.m.	B Oughterard, August 11, 7 a.m.	C Limerick, June 8, 7 a.m.	D Limerick, June 9, 7.10 a.m.	E Limerick, July 6, 7.10 a.m.
Max. height	5·0 km.	15·0 km.	17·0 km.	13·0 km.	21·0 km.
Minimum temperature ...	—	216° A (at 12·2 km.)	212° A (at 12·5 km.)	213° A (from 11·7 to 13 km.)	216° A (at 12·7 km.)
Place of fall	Clear Island, Co. Mayo	Moyvore, Westmeath	Kildysart	Buttevant	Cooleeney
Distance	? 50 km.	83 km.	31 km.	48 km.	56 km.
Direction *	? 0°	80°	280°	185°	68°
H_C, T_C	—	12 km., 217° A	12·5 km., 212°, 216° A	11·7 km., 213° A	12·7 km., 216° A

Notes—B. The heights above 8 km. are rather doubtful, as the original calibration marks relating to the pressure are uncertain, and the instrument was returned badly damaged. C. Wind E.N.E., light. Faint cirrus. D. Wind N.E., force 3. Cumulus, no high clouds. A rather different type of instrument was used, and the double record may be in part due to lag. E. Calm, cloudy, cirrus moving slowly from W.

* Direction 0° = N, 90° = E.

[1] From the tenth report of a committee presented at the Portsmouth meeting of the British Association, Dr. W. N. Shaw (chairman), Mr. E. Gold (secretary).

was presented the ascents have taken place. Six balloons were liberated, and five of these have been recovered.

It is desirable that observations of pilot balloons should be obtained in Ireland in addition to the records from registering balloons, and the committee recommend re-appointment, with a grant of 50*l.*, to permit of this extension of the work. A special theodolite, costing about 30*l.*, is necessary for the observations. The additional outlay on balloons and hydrogen for the pilot-balloon observations would be comparatively small.

In the table temperature is expressed in degrees centigrade above the absolute zero $-273°$ on the ordinary scale. H_c is the height and T_c the temperature at which temperature begins to be practically constant in a vertical direction.

A SCIENTIFIC MISCELLANY.

THE Smithsonian report for the year 1910 has just been published by the institution. Besides the report of the regents and the secretary, the volume contains, as usual, a "general appendix," consisting this year of thirty-four papers of popular interest on various branches of science, also biographies of a number of prominent scientific men who have recently died. Some of the papers are original, while others are reprinted from foreign and domestic scientific and technical periodicals. All the articles are selected with the view of furnishing the latest accurate information on topics which are believed to be of interest to a wide circle.

Aviation.

A review of modern progress in aviation is ably recorded by the late Mr. Octave Chanute. His paper covers the principal advances made in aviation, beginning with the experiments of Hiram Maxim in 1894, and including Langley's experiments (1896–1903), the author's own investigations, the work of the Wrights, Dumont, de Lagrange, Farman, Blériot, Bell, Curtiss, and others, bringing the subject down to the close of the year 1909.

Reclamation of Arid Lands.

Mr. F. H. Newell, director of the Reclamation Service, sets forth the recent progress in the reclamation of the arid lands in the Western States. The work of reclamation includes all the Western States and territories, where nearly 10,000 families are being supplied with water. Through this great undertaking the waste waters of the West are being conserved, destructive floods prevented, apparently valueless lands converted into productive farms, and thousands of families settled in newly opened territory, where they are maintaining homes on reclaimed land. Besides engineering, with its business and financial problems, the article deals with many other subjects, such as the character of settlers, the size of farms, crops, &c., and the individual projects which together furnish water for about 1,000,000 acres, nearly one-half of which is already settled.

Electric Power from the Mississippi.

A kindred topic is the great electric power plant at Keokuk, Iowa, with its 4278-foot concrete dam across the Mississippi River between Keokuk, Iowa, and Hamilton, Ill. This subject is treated by Mr. Chester M. Clark in a well-illustrated article entitled "Electric Power from the Mississippi River." The paper shows the development of the largest single hydro-electric plant in existence through the construction of what is undoubtedly the greatest bank-to-bank dam in the world.

Papers on Physics, Chemistry, and Astrophysics.

Under the heading of physics there is an account, by Mr. T. Thorne Baker, of experiments and researches in the telegraphy of photographs, transmitted by both the wire and the wireless systems; Prof. Jean Becquerel, professor at the Museum of Natural History of Paris, has permitted the translation of his valuable paper on modern ideas on the constitution of matter, comparing the old theories of matter with the newer views recently confirmed by experiments; and Mr. R. A. Millikan has abridged his treatise on "The Isolation of an Ion," which deals with the exact measurement of an elemental electrical charge and several analogous problems.

Dr. Charles E. Munroe, professor of chemistry at George Washington University, and a well-known authority on explosives, has written an interesting paper on the modern developments in methods of testing explosives.

Mr. C. G. Abbot, director of the Astrophysical Observatory of the Smithsonian Institution, contributes an article on the recently developed subject of astrophysics, which is a study of celestial physics, but pertains principally to the heat and other physical properties of the sun. The paper relates to the solar constant of radiation, a topic on which Mr. Abbot is well informed, having pursued studies in that direction for nearly sixteen years at the Smithsonian Observatory in Washington, and on Mount Whitney and Mount Wilson, California. In this article the author deals with the problem of measuring the amount of solar heat received by the earth and that lost in transit to it. The subject of astrophysics is further treated by Messrs. Curtiss, Deslandres, and Bosler in three articles.

What Constitutes the Earth?

Under the title "What is Terra Firma?" Mr. Bailey Willis, of the U.S. Geological Survey, attacks the old, yet modern, problem of the construction and balance of our globe in a review of current research in isostasy. In the discussion of this puzzling question Mr. Willis advances the theory that the foundation of all the continents is composed of solid rock which is self-crushed to a depth of about 120 kilometres, but rendered sufficiently rigid by pressure to maintain its form during prolonged geological periods with but slight change.

The Future Habitability of the Earth.

In line with the construction and condition of the globe, another author, Prof. T. C. Chamberlin, brings up the further vital question "The Future Habitability of the Earth" in an article in which he reviews the past, and considers the future, of the world as a dwelling-place for the human race. Many branches of science enter into the discussion; but upon geology, physics, chemistry, astronomy, and astrophysics rests the burden of the arguments. Prof. Chamberlin thinks that the earth will remain habitable for tens of millions of years, but concedes that the close approach of a celestial body to the sun would probably result in the disruption of the solar system and bring disaster to the earth. He further states, in regard to the future possibilities of scientific research, that "when moral purpose and research come to be the pre-eminent characteristics of our race by voluntary adoption and by the selective action of the survival of the fittest, and when these most potent attributes join in an unflagging endeavour to compass the highest development and the greatest perpetuity of the race, the true era of humanity will really have been begun."

Botany and Forestry.

Several papers come under the head of botany, among them an interesting sketch of the sacred ear-flower of the Aztecs, a plant the identity of which has been a mystery for years, and only recently rediscovered by the author, Mr. W. E. Safford, of the Bureau of Plant Industry. This little flower, resembling the human ear, has a remarkable history, and dates back to the early explorations of Mexico. It was first described in 1569 by Padre Bernardino de Sahagun, who states that it was much used owing to its delicious fragrance and its flavour when used as a spice. Despite the formidable name (Xochinacaztli) which it bears, the author suggests its cultivation on account of its unusual fragrance and pleasant spicy flavour.

Mr. Henry S. Graves, chief of the Forest Service, contributes a well-illustrated and original article on forest preservation, in which he carefully considers all points in the great problem, making many things clear which have long been obscure.

Medicine and Medical Researches.

Those interested in medical research and allied subjects will find matter of concern in the following papers:—manifested life of tissues outside of the organism, by Mr. Alexis Carrel and Mr. Montrose T. Burrows; epidemiology of tuberculosis, by Prof. Robert Koch; the significance of the pulse-rate in vertebrate animals, by Dr. Florence Buchanan; and sanitation on farms, by Dr. Allen W. Freeman.

Ethnology and Anthropology.

A comprehensive paper on the contemporary Slav peoples from a geographical and statistical point of view, by Mr. Ludor Niederle, of the Bohemian University of Prague, which has been translated from the Slavic language into English, funished new information on the history and distribution of these peoples.

Dr. J. Walter Fewkes, of the Bureau of American Ethnology, contributes a brief review of his recent work and investigations in cave dwellings, both at home and abroad. This paper is entitled "The Cave Dwellings of the Old and New Worlds."

The report also contains biographies of Melville W. Fuller, Sir W. Huggins, and Alexander Agassiz, together with papers on other subjects.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

It is announced that the sum of 300,000*l.* has been raised for the endowment fund for McGill University. The Duke of Connaught, in a telegram of congratulation to Mr. Angus, chairman of the McGill Campaign Committee, directs attention to the fact that this large sum was collected in five days.

In connection with the vacancy in the chair of mathematics at the University of Edinburgh, occasioned by the death of Prof. Chrystal, the curators of patronage of the University, in whom the patronage of this chair is vested, have decided to receive applications from intending candidates, along with testimonials, which should be lodged with their secretary, Mr. A. B. Fleming, 4 Albyn Place, Edinburgh, not later than Thursday, February 8, 1912.

We learn from *Science* that as a result of the action of the Michigan Board of Tax Equalisation, it is estimated that the University of Michigan will in the future receive 41,600*l.* more from the State for its maintenance than hitherto. From the same source we find that at the last session of the Legislature of the State of Minnesota, among other appropriations for the University was one which will produce 1000*l.* for each of the two years before the next Legislature assembles to be voted exclusively to research, not agricultural, since that is cared for otherwise. Our contemporary also states that by the will of Miss Phoebe Caroline Swords, of New York City, 4000*l.* is bequeathed to Columbia University.

A dinner was given at the Savoy Hotel on November 23 in aid of the fund for the erection and endowment of new buildings for Bedford College for Women. The sum of 100,000*l.* is required to complete the new buildings and provide the required endowment; and of this amount 50,000*l.*, including a grant of 20,000*l.* from the London County Council, had been secured before the dinner. The London County Council has promised a further 10,000*l.* if a like sum should be obtained without delay. The primary object of the dinner was to raise the amount necessary to secure the second donation from the London County Council; and it is satisfactory to record that at the conclusion of the dinner more than 7000*l.* had been subscribed. But 30,000*l.* will still be required, even after the second contribution from the London County Council has been received.

The most recent addition to its educational series published by the Manchester University Press is entitled "Outlines of Education Courses in Manchester University." The syllabuses of which the volume, running to 189 pages, is composed have been prepared to assist the lecture and demonstration courses given in the department of education of the university; and they are intended for the use of students. The first syllabus covers Prof. M. E. Sadler's course on the history of education in England from 1800 to 1911, and consists of exhaustive notes on each lecture, together with an invaluable bibliography directing the student to works of reference where the subjects touched upon can be studied in greater detail. Students of education everywhere will welcome this complete guide to the study of the history of education. Prof. Findlay's notes on his lectures on the principles of education are somewhat briefer, and will give the students much more to do for themselves. Here, too, frequent references to standard works on pedagogy will prove of the greatest service. The remaining discourses are more miscellaneous in character, and are dealt with in a less extended manner. The publication of the syllabuses, and the invitation extended in an introductory note to educational workers generally to criticise and advise, may be taken as a welcome indication that earnest efforts are being made in our universities gradually to build up a science of education founded upon experience and experiment.

The annual report on the 115th session of the Glasgow and West of Scotland Technical College has now been circulated. We notice that for the academic year 1910–11 there was an increase in the numbers of both day and evening students. The success with which the governors have established cordial relations with local employers of labour is very marked. For a number of years past the requests from employers for the nomination of qualified students in chemistry to fill industrial posts have been greater than the college could satisfy, and a similar position is arising in the engineering sections of the college. Most of the appointments thus gained are in works in the district, but a considerable number are abroad. Manufacturing firms in the district are recognising in increasing measure, also, the ability of the college to assist them in many of the problems arising in their industrial operations. Requests have been made to the college for reports and advice on a variety of subjects, in addition to simple questions on the strength of metals and of building materials, the accuracy of measuring instruments, and so on. Another satisfactory feature of the strengthening relations between the college and employers is the increasing number of firms which now request reports upon the attendance and progress of their apprentices at college classes. The report shows that new courses of a technical kind are arranged as soon as a new demand arises, continual additions are made to the already extensive equipment, and the building scheme is now completed. The financial position of the college appears to be in an equally satisfactory state.

We have received a copy of the report for the session 1910–11 of the work of the department of technology of the City and Guilds of London Institute. During the session 4495 classes in technological subjects were registered in 316 towns. These classes were attended by 52,680 students. So far as the examinations conducted by the institute during the year were concerned, the report shows 24,342 candidates were presented in technology from 465 centres in the United Kingdom, and of these 14,206 passed. By including the candidates from India and the Dominions overseas, and those for the teachers' certificates in manual training and domestic subjects, the total number of examinees was 27,205. This figure shows an increase on those of any previous year. During the session, too, ninety-one centres were visited by members of the institute's staff for the examination, inspection, or organisation of classes, several centres receiving two or three visits in order to complete the inspection. The report again directs attention to the criticisms and suggestions received from the examiners of the institute. We can here quote only two examples:—"Teachers would, for instance, be well advised to keep their knowledge thoroughly up to date by studying the transactions of the leading technical societies and institutions, and the articles in technical journals, and not confining themselves to text-books. In many subjects teachers should also, if possible, give more practice to students in expressing their ideas, in arithmetical work, and in careful sketching, *e.g.* by requiring the presentation of well-illustrated notes of lessons." The want of suitable and adequate preliminary education exhibited by students presenting themselves for entry into technical classes is again commented upon.

The International Council of Women has done a piece of very useful work in issuing a pamphlet on "National Systems of Education" (Aberdeen: Rosemount Press, price 3*d.*). In response to a form of inquiry drawn up by Mrs. Ogilvie Gordon, representatives of the women's organisation in most European countries, in the great self-governing communities of the British Empire, and in the United States have given us brief *résumés* of the actual

position of education in their respective countries, the whole constituting (within its limits) a valuable document for a comparative study of educational systems such as the intelligent non-expert might wish to make. Thus we find that Austria is the only European country which has compulsory evening continuation schools for boys from fourteen to sixteen years of age. In Germany, practice differs in different States, but where continuation schools are compulsory they are *day* schools, something after the pattern of our half-time schools, though, of course, the pupils are older. Primary education is compulsory in most countries, though Belgium still stands for the principle of freedom. In Russia and Finland, also, it is not yet compulsory; but in Finland it is the question of the hour, and in Russia compulsion in this matter was amongst the projected reforms of the murdered Minister Stolypin. It is interesting to note, too, that compulsory school begins earlier in England than in any other European country. In Russia elementary schools only provide for children from eight to eleven years of age. We note that the pamphlet does not include France or Italy, and that the various communications are not dated. The statement that English teachers (men) in elementary schools receive 175*l.* a year, rising by annual increments of 5*l.* to 200*l.*, would surely surprise the officials of the National Union; and the Board of Education Library is no longer in Cannon Row.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, November 8.—Prof. W. W. Watts, F.R.S., president, in the chair.—Prof. E. **Hull**: The interglacial gravel beds of the Isle of Wight and the south of England, and the conditions of their formation. The origin and mode of formation of the gravel terraces of the Isle of Wight and the New Forest districts are still open to discussion. The levels of the higher beds on both sides of the Solent up to about 400 feet indicate the amount of subsidence of the whole area at a time when the stratified gravels, composed mainly of rolled flints, were formed at the margin of the uprising ridges of the Chalk in the post-Glacial epoch, for this part of England. Preceding this was the great uplift by which the British Isles were joined to the Continent as land. By this uplift the English Channel was laid dry, and along its centre there ran a river from its source about the Straits of Dover to its outlet into the ocean through the continental platform. The gravel beds of this district are considered to be the representatives of the high-level gravels of the Midlands and Cromer, also of the "interglacial gravels" of Cheshire and Lancashire, and the shell-bearing beds of the Denbighshire Hills, and of Moel Tryfaen in Wales, at levels of about 1200 feet above the sea.—J. B. **Scrivenor**: The Gopeng beds of Kinta (Federated Malay States). Gopeng is a prosperous mining centre in the Kinta Valley, close to the granite of the Main Range of the Malay Peninsula. It is shown that not only are the Gopeng beds cut by veins from the granite and altered at the junction with the granite, but they are also faulted down against the limestone. The Gopeng beds, consisting of clays and boulder-clays with some stratified drift, are of glacial origin. This is proved by the inclusion of large boulders in the clay, the physical condition of the components of the clays and their distribution, and by the resemblance of the beds to Pleistocene glacial detritus. No boulders have been found showing striation due to ice action, nor has any glaciated rock-surface been found. The boulders are all decomposed owing to the power of the ground-water in removing silica; and, if the limestone ever presented the features of a glaciated surface, it has been modified by solution owing to the action of ground-water. The petrology of the Gopeng beds is described. The ice from which the detritus was derived passed over a stanniferous granite mass, and the Gopeng beds carry tin-ore throughout. The tin-ore is an original constituent of the beds, but they have been further enriched by tin-ore derived from the Mesozoic granite at their junction with the granite and in the neighbourhood of veins from the granite that have risen through the limestone. The Gopeng beds are considered to be the equivalent in time of the Talchir boulder beds of Orissa; but a petrological similarity is wanting.

Physical Society, November 10.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Prof. **Coker**: The effect of holes and semicircular notches on the distribution of stress in tension members. For the experimental determination of stresses in loaded members an optical examination of a model shaped in transparent material has advantages. Two cases of importance are examined in this way, and the results are compared with those obtained by analysis. The first example relates to the case of a hole in a tension member subjected to a uniformly applied stress p. The values of $(p_x - p_y)$, the difference between the principal stresses, are obtained optically, and they show agreement with the calculated values if the diameter of the hole is not greater than one-quarter of the width of the plate; but beyond this the agreement is not good. For practical purposes it is important to be able to estimate the maximum stress from the value obtained by assuming that the total load on a tension member is uniformly distributed over the cross-section. A formula based on the relationship found in the experiments takes the form

$$p_{\max} = \frac{6c^3}{2c^3 + 2c^2 + c + 1} p_{\text{mean}},$$

where c is the ratio of the width of the member to the diameter of the hole; if c is large compared with unity this reduces to the simple form

$$p_{\text{mean}} = \frac{3c}{c+1}.$$

In the case of two semicircular notches, arranged symmetrically with regard to the centre line and to the cross-section, there appears to be no exact mathematical solution; but an approximation has been obtained by Leon, resulting in expressions for p_x and p_y at the minimum section of the form

$$p_x = \frac{p}{2}\left(2 + \frac{a^2}{r^2} + \frac{a^4}{r^4}\right), \quad p_y = \frac{p}{2}\left(\frac{a^2}{r^2} - \frac{a^4}{r^4}\right),$$

provided that the radius of the notch is small compared with the breadth of the plate. Experimental determinations of $p_x - p_y$ show that the maximum values agree with those of the formulæ for notches having a maximum radius of about one-quarter of the breadth of the member, but the minimum values do not show good agreement if the notch has a radius greater than one-eighth of the breadth. The results appear to indicate that the radial stress for large notches is greater than that given by the formula. For determining the maximum stress from the applied mean stress a formula is proposed of the form

$$p_{\max} = \frac{12c^3}{6c^3 + 4c^2 + c + 1} p_{\text{mean}},$$

and this shows a fair agreement with the experimental values.

Royal Anthropological Institute, November 14.—Mr. R. W. **Williamson**: Mafulu mountain people of British New Guinea. The paper refers to an inland tribe of whom very little has hitherto been known, but among whom the author spent some time last year. The Mafulu are a short-statured people, sooty-brown in colour, with grizzly, brownish hair. The clothing of both men and women consists merely of a narrow band of bark cloth, passed between the legs and tied round the waist. They are cannibals, but not head-hunters. They live in scattered clusters of villages perched up in the summits of the mountain ridges, and are divided into clans, each clan having its own chief and village club-house. They bury their dead underground except as regards chiefs and important people, whose bodies are put into boxes fixed above ground, on clusters of poles in the village enclosure or in a species of fig tree. The author described some of their curious feasts and ceremonies, including the "Big Feast," at which the supports of one of these boxes are cut away so that the box and its contents fall to the ground; then the skull and bones within it, and those of all their other important dead, are smeared with the blood of slain pigs, after which the evil-disposed ghosts of their owners will no more disturb the people. The author suggested the possibility of these people having a partial pygmy or negrito ancestry.

Mineralogical Society, November 14.—Anniversary meeting.—Prof. W. J. Lewis, F.R.S., president, in the chair. —R. H. **Solly**: Dufrenoysite, associated with seligmannite, from the Binnental. In a small cavity, discovered in August, in the dolomite rock in the Lengenbach Quarry, were a few brilliant crystals of dufrenoysite, coated on their fractured surfaces with minute crystals of seligmannite. Measurements of two crystals of the former led to the discovery of twenty-six new forms.—H. G. **Smith**: A simple graphic method for determining extinction-angles in sections of biaxial crystals. A means of drawing a crystal projected on any plane and finding the extinction-directions was explained.—Dr. G. T. **Prior**: The meteoric stone which recently fell in Egypt. A meteorite fell on June 29 near the village of Abdel Malek, about 44 km. E.S.E. of Alexandria. It exhibits a brilliant, varnish-like crust, and consists mainly of a coarse-grained crystalline aggregate, without chondrules, of a green pyroxene and a brown ferriferous olivine with only a little felspar and practically no nickeliferous iron. A quantitative analysis showed that the stone includes a high percentage of lime, and that the green pyroxene, containing much lime as well as ferrous oxide and magnesia, constitutes about three-quarters of the stone by weight. A study of thin sections under the microscope showed that the pyroxene is generally twinned on 100, gives extinction angles as high as 35°, and exhibits "herring-bone" structure owing to fine twinning on 001.—T. **Crook** and S. J. **Johnstone**: Strüverite from the Federated Malay States. A mineral of doubtful identity found in the course of tin-mining on the Sebantum River, Kuala Kangsar district, Perak, was proved to be strüverite; it closely resembles the mineral recently recorded by Hess and Wells from South Dakota, U.S.A.—A. **Hutchinson**: The temperature at which gypsum becomes optically uniaxial. A small plate of gypsum, cut normal to the acute bisectrix, was placed in a glass-topped cell, through which a stream of water at a determinate temperature was passed, and the optic picture was studied under a microscope. The plate became uniaxial at 25° C.—A. **Hutchinson**: A total-reflection diagram. From this diagram the refractive index of a substance is graphically determined when given the angle of total reflection with respect to a known substance of higher refractive index. By taking the sine of the angle as coordinate, the curves are straight lines.—T. **Crook**: The occurrence of ankerite in coal. The white crystalline layers often found as infillings of the vertical joints in British coal are ankerite. Dolomite was not found, and calcite occurs sparingly as compared with ankerite in the specimens examined.

Royal Microscopical Society, November 15.—J. E. **Barnard**: A geometric slide photomicrographic apparatus. The apparatus was designed on the principle of the geometric slide throughout, as enunciated by Lord Kelvin and Tate. The base of the apparatus was formed of two castings designed on the girder principle, braced together at each end and in the middle. The portion to carry the microscope was also formed by a pair of castings braced together in the same way. Great rigidity was obtained, and the whole apparatus would move together if subjected to shock or vibration. Rods were fastened down on the top of the castings to support the apparatus, and the camera slid along these on two V-grooves on one side and on a plane surface on the other side. The camera was supported on vertical rods fixed on the geometric slides. The apparatus could be used equally well as a horizontal or vertical camera, or at an angle of 45°.—Rev. Hilderic **Friend**: Fridericia. The genus Fridericia was created by Michaelsen in 1889 to receive certain species of Enchytræids, eleven in number, possessed of dorsal pores and having setæ of unequal lengths. In 1895 Beddard reckoned twelve species, but not one was known as British. Moore, Friend, and others added to the list, which in 1900 stood at twenty-one. Bretscher, Issel, and others then took up the study, and at the present time some seventy or eighty species of Fridericia are known to science. The largest is *F. magna*, Friend, which has been found in England, Ireland, and Scotland, but so far has not been reported abroad. The author, whose researches into this genus began in 1896, here records no fewer than thirty species found up to the present time in the British Isles. Some of these are new to science; and a series of keys is appended to enable the student readily to distinguish the allied species.

Linnean Society, November 16.—Dr. D. H. Scott, F.R.S., president, in the chair.—Dr. R. R. **Gates**: Certain aspects of the mutation problem in Œnothera. Work with the Œnotheras has developed in several directions, all bearing on the general question of the place to be assigned to mutation as an evolutionary factor. A concerted attack upon the behaviour of the Œnotheras in heredity and variation from several points of view gives a broader basis for the interpretation of the evolutionary significance of these phenomena than has hitherto been possible in most other genera. The cytological evidence has shown that in most of the mutants from *Œnothera Lamarckiana* the chromosome number is unchanged, but in the mutant *Œ. gigas* it is doubled. Hence mutants originate in various ways. Evidence goes to show that the chromosome doubling in *Œ. gigas* probably occurred either in the fertilised egg or in a megaspore mother-cell, which afterwards developed apogamously. On the other hand, in certain cases the mutational change probably occurred during the reduction divisions. Thus *Œ. rubricalyx* is a mutant from *Œ. rubrinervis*, which produces an extreme amount of pigment; and when crossed with the parent type the new character behaves as a Mendelian dominant, and in such a way as to show that the original mutant individual was heterozygous, and probably originated from a cross between a germ-cell in which the new dominant character appeared and one in which it was lacking. From this and much other evidence mutation in Œnothera appears to be due to a general condition of germinal instability, which in turn is probably connected with crossing in the ancestry. This, however, by no means deprives it of evolutionary significance, for all open-pollinated species of plants are hybrids in the sense that various races have participated in their immediate ancestry. Certain results were also communicated of *Œ. grandiflora* × *Œ. rubricalyx*, *Œ. Lamarckiana* × *Œ. grandiflora*, and other crosses which produce twin types.—G. Claridge **Druce**: Some floristic results of the International Phytogeographic Excursion through the British Isles.—A. W. **Hill**: Drawings of a viviparous specimen of *Juncus bufonius*. The seedlings were seen emerging from the parent capsule.—N. C. **Macnamara**: Mutations in foxglove plants. From a packet of foxglove seeds (*Digitalis purpurea*) sown in the year 1906, fifty-four plants were, in June, 1907, planted in a shrubbery of fir trees with an undergrowth of laurels. Of these plants fifty-one grew into normal foxgloves, but the three remaining plants were sports, which we may distinguish by the letters A, B, and C. A. In this plant the flowers of the lower half of the stem possessed only a bifid upper petal and seven stamens united at their bases. The flowers of the upper part of the spike were normal. B. A fine, well-grown plant 4½ feet high; throughout the whole length of the spike the flower consisted of a bifid upper petal, seven stamens, and style. The upper part of this spike was isolated; it produced abundant self-fertilised seed. C. The spike of this plant grew to be 5 feet high; from base to apex its flowers consisted of nine stamens and a style, with no vestige of petals. It seems that a certain number of the foxglove seeds sown in the year 1906 contained elements in a condition such as that described by de Vries as being "impressed by an impulsive mutability," for some of the flowers produced by these seeds were sports. Seeds from these sports produced their like in 1909; and, further, these latter plants produced some terminal flowers totally differing in character from the parent sport from which they were derived. Seeds from these terminal flowers produced their like in the year 1911; so that there are now two different strains of foxglove plants produced from the seeds sown in 1906, and these strains have been produced from self-fertilised flowers, that is, from flowers carefully protected from insects or other means of cross-fertilisation.

DUBLIN.

Royal Irish Academy, November 13.—Rev. Dr. Mahaffy, president, in the chair.—R. Lloyd **Praeger**: Phanerogamia. Part ii. (Clare Island Survey.) On a former occasion the question of the origin of the island flora,

and the influence upon it of human operations, had been dealt with. In the present communication the composition of the flora of Clare Island, the plant societies, and the relation of the flora to that of the adjoining islands, were dealt with. The floras of all the islands is remarkably large in comparison with those of adjoining mainland areas, pointing to former easy migration by means of post-glacial land-connections.—The following papers were also read, in connection with the Clare Island Survey:—Claude **Morley**: Hymenoptera.—D. R. **Pack-Beresford**: Arencida and Phalangida (Spiders and Harvestmen).

PARIS.

Academy of Sciences, November 20.—M. Armand Gautier in the chair.—J. B. **Charcot**: The laboratory for scientific maritime researches of the *Pourquoi-Pas?* It is suggested that the vessel *Pourquoi-Pas?* which served for the last French Antarctic expedition, would form a very serviceable laboratory for marine biological researches. Its present equipment is described, and an appeal for the necessary funds is made.—M. **Borrelly**: Observations of the periodic Borrelly comet (1911*e*) made at the Observatory of Marseilles with the comet finder. Data are given for November 13, 14, 15, and 16. The comet is moderately bright, of the tenth magnitude, its extent being 2′.—P. **Montel**: Some analytical functions which admit of two exceptional values within one region.—G. **Kœnigs**: Surfaces which, in the course of a given movement, are continually osculating to their conjugated profile.—Raoul **Bayeux**: An apparatus of precision for the use of gaseous oxygen in physiology and therapeutics. In the instrument described and illustrated the usual indiarubber bag is replaced by a small cylinder of compressed oxygen controlled by a double metallic governor composed of two capsules similar to those used in the aneroid barometer. There is a specially designed sensitive tap for the distribution, and the amount of gas available at any instant can be read directly.—C. **Gutton**: The velocity of propagation of electromagnetic waves along a line of metallic wires.—V. **Auger**: The action of hydrogen peroxide upon the oxygen compounds of iodine. Details are given of the interaction of hydrogen peroxide with neutral and basic alkaline periodates, periodic acid, and iodic acid.—MM. **Desgrez** and **Feuillié**: The estimation of urea. The methods of Folin, Mörner, and Sjœqvist are exact, but require too much time for biological investigations, necessitating a large number of estimations. The method described is based on the use of Millon's reagent. It has been objected that Millon's reagent acts upon other nitrogenous substances besides urea, but experiments made with salts of ammonia, uric acid, creatine, creatinine, hypoxanthine, tyrosine, xanthine, leucine, guanine, and allantoin showed that the last-named substance alone interferes. The proportion of allantoin in human urine is so small that this complication cannot be considered as a real objection to the process. The necessity of suitably fixing the temperature at which the reaction is carried out is emphasised.—Marcel **Godchot** and Félix **Taboury**: Some derivatives of cyclopentanone. In a previous communication a new ketone, $C_{10}H_{16}O$, was obtained by the hydrogenation of cyclopentanone by the method of Sabatier and Senderens, and its constitution was provisionally suggested as α-cyclopentylcyclopentanone. In the present paper this formula is confirmed by additional experiments.—J. **Vallory**: Studies in the reproduction of *Chaetomium kunzeanum*, var. *chlorinum*.—P. **Desroche**: The mode of action of coloured light on the Chlamydomonas. Blue rays have a paralysing action on the zoospores, whilst the red rays have a stimulating action.—J. **Tournois**: Floral anomalies of *Humulus japonicus*.—C. L. **Gatin** and M. **Fluteaux**: The anatomical modification produced in certain plants by the dust from tarred roads. It has been shown in a previous communication that the trees in certain parts of the Bois de Boulogne have been adversely affected by the action of the dust from the treated road. In the present paper it is shown that these effects are accompanied by certain anatomical modifications in the plant.—E. **Milliau**: The detection of carbon bisulphide in oils.—E. **Vasticar**: The structure of Corti's fibres.—R. **Robinson**: New arguments in favour of the action of the suprarenal capsules on the determination of sex. A summary of the facts known on the relation between the condition of the suprarenal capsules and the sex of the embryo.—A. **Pézard**: The determination of the secondary sexual characters in the Gallinaceæ.—Anna **Drzewina**: Rapid modifications of form under the influence of deprivation of oxygen in a Medusa, *Eleutheria dichotoma*.—Albert **Frouin** and Arthur **Compton**: The loss of activity of trypsin by dialysis into distilled water, and the regeneration of the activity by the addition of salts. From the experiments described the authors conclude that the presence of salts is necessary for the trypsin to exert a proteolytic action.—Louis **Germain**: Atlantis. A review of the principal palæontological and zoological arguments in favour of the actual existence of the vanished continent, Atlantis.—Maurice **Piettre**: The melanins.—A. **Moutier**: The mechanism of general or local troubles of the arterial circulation leading to general or local arterio-sclerosis. Instruments such as sphygmomanometers are generally regarded as measuring the pressure of the blood in the interior of the artery. This the author has shown to be erroneous, the force of compression being exclusively a function of the elastic state of the arterial wall, and independent of the manometric pressure. Additional experimental evidence in favour of this view is given.—Ch. **Moureu** and A. **Lepape**: The ratios of the rare gases between themselves and with nitrogen in fire-damp. The examination of the inert residues from six samples of fire-damp shows that the crude nitrogen from the fire-damp presents a striking analogy with crude nitrogen from other natural mixtures.—Alfred **Angot**: The earthquake of November 16, 1911. The true amplitude of the horizontal movement of the ground at Paris was of the order of a millimetre.

CAPE TOWN.

Royal Society of South Africa, October 18.—Prof. H. H. W. Pearson, vice-president, in the chair.—J. **Moir**: The spectrum of ruby. Part iii. Two further very faint spectrum lines are described. The artificial ruby has been analysed, and chromium detected as the colouring matter. When a ruby is heated above 300° C. it changes, through scarlet and brown, to the colour of chromium glass, and all the characteristic spectrum lines disappear. It recovers completely on cooling. The effect of heat on the birefringence of corundum has been studied, and has been found to be insignificant The spectrum of ruby is therefore due to chromium in a special atomic condition, which does not apparently occur elsewhere in nature.—Dr. and Mrs. J. R. **Sutton**: Some causes and effects of variation in the range of temperature. The paper contains the results of a discussion of some of the more salient meteorological aspects of a variation in the range of temperature. It deals in a general way with the changes of temperature, moisture, pressure, and sunshine, which go with a variation in the range of temperature, monthly means being used. Harmonic constants of barometric pressure and temperature are computed for months of great and small range of temperature respectively.—R. T. A. **Innes**: Algebraic development of the elliptic perturbative function used in the theories of planetary motion. The paper presents tables whereby the functions which operate on the ratio of the semi-axes can be easily calculated to any order of the eccentricities and mutual inclination, so far as regards primary and secondary terms, which alone have any importance in the planetary theories. The paper concludes with an explicit development of the secular part of the perturbative function to any order.—B. de St. J. **Van der Riet**: A supposed new mineral from Du Toit's Pan, Kimberley. The supposed new mineral from Du Toit's Pan, Kimberley, reported in NATURE of September 7 by Mr. J. R. Sutton, appears to the author to be derived from a well-known artificial material, viz. commercial calcium carbide. It is certain that acetylene generators have been in use on the mine for years, and it is quite possible that a portion of the waste from the acetylene machines has in some manner found its way to the pulsator, where the supposed mineral was discovered. It has been found possible to compare specimens of the substance referred to (kindly supplied by the general manager of De Beers' Co.) with the lumps and pellets which settle in the lime residue from generators supplying acetylene gas to the chemical laboratory of Victoria College. In

chemical as well as physical characters there is an unmistakable similarity between the two products. Thus (1) slaked lime, which, of course, accompanies carbide pellets, can be detected in some of the cavities on surfaces of the pulsator pellets. (2) Variations in hardness, form, colour, fracture, size of pellets, and peculiar markings are faithfully reproduced. (3) In either case the lumps and pellets vary in composition from iron carbide, attacked by dilute acids, to iron silico-carbide, which is attacked by hydrofluoric acid, but not by hydrochloric and sulphuric acids. (4) The pellets from either source give off an odour of acetylene when crushed. (5) The pulsator pellets, as well as ordinary carbide pellets, do not contain, so far as can be found, notable quantities of titanium. In an iron mineral derived from the ilmenite of "blue ground," by reduction at a high temperature, one should certainly expect to find titanium.—J. C. **Beattie**: Further magnetic observations in South Africa during the years 1910 and 1911. The communication contains the reduced results of observations in various parts of South Africa during 1910 and 1911 for determining the secular variation of the magnetic elements. It also contains results of additional observations in the West Transvaal and the east of Cape Province, with a discussion of the magnetic states of these regions.—W. A. Douglas **Rudge**: Action of radium salts on glass. An account of experiments carried on during the past three years in order to study the prolonged action of radium salts upon glass. Small quantities of radium were sealed up in thick-walled tubes, and the extent to which the coloration extended determined by cutting up sections of the tube, polishing the ends, and examining with a microscope. The tint developed depended upon the nature of the glass employed, and the depth of penetration depended upon the structure of the glass. Many kinds of glass show a "zonal" structure, and an abrupt change in the depth of coloration appears at the junction of successive zones. The width of the zones were measured with a micrometer, the first and darkest being 0·27 mm.; the others extended right up to the external walls of the tube, a distance of 2·48 mm. from the bore. If the coloration is due to X particles alone, the range must be much greater than would be deduced from the experiments of Rutherford and Joly. There is evidently some obstacle met with to the free passage of the rays at each zonal layer, as the coloration shows. The action of even a very impure radium salt is comparatively rapid; a few milligrams of a salt, containing about one-thousandth of its weight of radium, causes a very definite coloration at the end of twenty days, the first zone being then clearly defined. The coloration must be due to B and Y, as well as X, rays and emanation.—J. **Burtt-Davy**: A new species of Mesembryanthemum from the Transvaal, and notes on the genus Ficus.

New South Wales.

Linnean Society, September 27.—Mr. W. W. Froggatt, president, in the chair.—Archdeacon F. E. **Haviland**: Notes on the indigenous plants of the Cobar district. The Cobar district may be said to comprise the country within a 50-mile radius of the town of Cobar, embracing an area of about 6000 square miles. It is flat, with occasional hills rising abruptly. The town of Cobar is 805 feet above sea-level, and the distance from the coast about 420 miles. The district is droughty, with prevailing high temperatures and a dry atmosphere, the average annual rainfall being about 14 inches. The flora is a typical inland, dry-country flora, the general appearance of the vegetation being that of brushwood, few trees of any kind attaining any considerable dimensions. The plants met with represent 161 genera and 284 species of Dicotyledons, 30 genera and 47 species of Monocotyledons, and 5 genera and 6 species of Acotyledons.—R. H. **Cambage**: Notes on the native flora of New South Wales. Part viii. Camden to Burragorang and Mount Werong. One of the features brought out is the marked influence of climate upon plant distribution, for, as the mountain is ascended, the vegetation is found to correspond more nearly with that of Tasmania, where a similar climate prevails. Between Camden and Burragorang, at altitudes ranging up to 1800 feet, 30 per cent. of the species are Tasmanian; but between Colong and Mount Werong, at altitudes varying from 2000 to 4000 feet above sea-level, about 48 per cent. of the plants seem to belong to species which occur in Tasmania. Reference is made to the occurrence of the narrow-leaved ironbark (*Eucalyptus crebra*) around Colong at altitudes up to 2500 feet, which is unusual in latitudes south of Sydney; its presence may generally be regarded as an indication that the rock producing the soil upon which these trees grow contains upwards of 60 per cent. silica. Although it will thrive on rather poor siliceous soils, it is absent from excellent basaltic soil a few yards away, but which contains less than 45 per cent. silica; and the question is raised whether it may not be rather the physical conditions of the soil than the chemical constituents which regulate the distribution of this tree.—R. J. **Tillyard**: The genus Diphlebia (Neuroptera: Odonata), with descriptions of new species and life-histories. The genus Diphlebia is one of three closely allied genera, grouped by de Selys to form the sixth legion (Amphipteryx) in his classification of the subfamily Calopteryginæ—Devadetta (=Tetraneura of Selys) from the Malay Peninsula, Siam, and Borneo, Amphipteryx from Colombia, and Diphlebia from Australia, represented, hitherto, by two species. Two additional species of the last of these are described as new, one from Kuranda, North Queensland (Dodd), and the other from rocky creeks in the Nandewar Ranges, New South Wales. The life-history of the latter has been worked out. In the Anisoptera, the characters of the larval gizzard determine the separation of the main groups. The same test should be applied to the unsatisfactory classification of the Zygoptera.

BOOKS RECEIVED.

Chemistry Note-book. By E. J. Sumner. Pp. 92. (Burnley: Cooper Printing Co., Ltd.) 2*s*.

HEALING BY TOUCH.

The King's Evil. By Dr. Raymond Crawfurd. Pp. 187. (Oxford: The Clarendon Press, 1911.) Price 8*s.* 6*d.* net.

THE history of the king's evil and the royal touch, whether as a picture in detail of a certain stream of a very ancient tradition, or as a particular instance of something more than a tradition or symbol, of a mystic interpretation of man's relation to the unseen powers which encompass him, is a deeply interesting study. We are far from imputing it as a fault to Dr. Raymond Crawfurd if, in his scholarly decision to keep to his own part of a great subject, and to do thoroughly what he undertook, he has averted his eye from the ancient sources of the mystery, or even neglected the facts and fables which linked up the modern and the ancient modes of miraculous healing. Still, has not Dr. Crawfurd almost dissembled these sources of the far past and the ancient myth? He remarks, for instance, that the gods "have transmitted the gift" (of healing) to mortal man—especially to conspicuous individuals such as kings; to Pyrrhus, for example, or Vespasian. And a few sentences farther on (p. 10) he says that, with the spread of Christianity, the priest "usurped" for a while the prerogative of healing. This seems scarcely the right colour to put upon the past. Samuel looked upon Saul as the usurper of intercessory functions. And the gift of healing was not so much a "transmission" from gods to men as that in this function the priest-king originally was the organ rather than the agent of the supernatural; originally the potency was not so much a delegation as a continuity.

The laying on of hands, as practised for disease in England and France, and as still practised in the institution of Holy Orders, passed by insensible gradations from gods and godlings to heroes and men. Any kindred touch might convey its influence, even the touch of a relic of the operative personage. From this point of view, in Greece, *χεὶρ* and *δύναμις* were equivalent. And in various times and circumstances the manual act might pass a stream of virtue from healer to patient, or might be a manumission, or a protective gesture, or merely a symbol. Clearly, in the idea of the royal touch, it stood for more than a symbol.

The "soothing-handed" (*ἠπιόχειρει*) Chiron, Eileithyiæ, Apollo, Hygieia, poured forth their virtue to Asclepius, Serapis, the mother of God (*χεὶρ τῆς Παναγίας*), Cosmas and Damian, and onward, until we take up the modern part of the story with Dr. Crawfurd, from Robert the Pious (996–1031 A.D.). If in view of the inclination of the readers of NATURE towards evolution I have ventured to knit up a few of these ancient links, from the beginning of his own story Dr. Crawfurd is an indispensable guide. From the first we feel we are in good hands; the scrupulous references to authorities, the exploration of the sources, many of which the author has either brought to light or has set in their proper light, the first glance at the scholarly translations from the Latin, or at the excellent bibliography, and, above all, the sound criticism not unspiced with humour, give the reader a sense of completeness and sureness. The subject of the royal touch had not been adequately treated; Dr. Crawfurd has been fortunate in his subject, and has produced an exhaustive and probably a final study of it.

Magic touch in ancient times was valid not for a few but for all or any diseases and for parturition. In the Middle Ages, however, it had become restricted to jaundice—the *morbus regius*—and to bubos. For the jaundice the touch soon fell out of use; the bubos were chiefly of the scrofulous kind, but Dr. Crawfurd supposes that not a few ambulant cases of bubonic plague (*lues inguinaria*) were included in the crowd. At a later date probably syphilis came in, a disease not mentioned, I think, by the author, though as he has forgotten an index—the only defect in his scholarly apparatus—I cannot be sure of this. In one of the Continental galleries I remember a picture, of the early sixteenth century, commemorating a cure by a miracle-working saint, in which the patient exhibited in his own person a fine specimen of syphilitic ulceration and of the painter's veracity.

If we regard the laying on of hands as an ancient prerogative, one deriving from the larger function of "Binding and Loosing," we attach less importance to the defects of the records of its appearance in modern times; we guess that this mystery never died out; that the lack of records is due to their destruction, or to silence on matters of familiar custom. Still, Dr. Crawfurd is as precise as sources will allow, and it is not without interest to note that, if in France the definite history of the touch begins with Robert the Pious, yet the legends of the times of Clovis suggest in this respect also the continuity of Gallo-Roman ritual. With Clovis, as with later kings of England and France, with Queen Anne for instance, the assumption of this prerogative may have been to prove that he too was hedged about with divinity. England, in her comparative isolation from the Roman tradition, records no royal touch before Edward the Confessor.

If it was not until much later times that the kings became specialists in scrofula the previous vagueness depended largely on that of contemporary diagnosis. And here we come to matter of interest to our faith-healers of to-day; to the partnership of physician and priest or king—priest or king as the touch was, generally speaking, conducted under an imposing courtly and religious ceremony. Dr. Crawfurd carefully reproduces the Offices as modified from time to time, and he tells us that the enthusiasm of the sick was thus exalted to an amazing passion. Moreover, the king's physicians took a prominent part, not only in protecting him from crowds of sufferers of a nondescript kind, or of kinds not amenable to the royal touch, but actively in securing this blessing for the cases in which their skill had failed, and for persons in whom they were interested. Passing over earlier and cruder ages, we may descend in time to so great

G

a man as Wiseman, the really distinguished, sagacious, and learned sergeant surgeon to Charles the Second, who said of his master's potency, with probably more than a courtier's sincerity, that "he cureth more in any one year than all the Chirurgions of London have done in an age." This testimony is the more remarkable as Wiseman was not himself officially concerned with the ceremony. In one passage, indeed, Wiseman attributes a relapse to the loss of the angel from the neck of the patient. Like Alexander of Tralles, good doctor as for his time he was, he still clung to amulets and such magic. We read then with no surprise the devout appreciations of such men as Fuller and Collier. Shortly before Wiseman, we have the curious story, one better known to medical men, of the arraignment of one Leverett, at the instance of William Clowes the Younger, surgeon to Charles the First, before the College of Physicians for his imposture, which this august body had no difficulty in proving by convincing evidence of facts, in pretending to vie with the king in the power of curing the evil, even by methods still more magical. We do not find, however, that the College did the fairest thing in its power; it might have put the King and Leverett severally to trial on the same patient or patients. But, as Clowes aptly remarked, Leverett was not even a seventh son of a seventh son; he proved to be only the fourth. He was a hollow rogue.

Still, the sceptic had crept near the ears of his world, even at an early date; not always knowing himself to be a sceptic. John of Gaddesden (under Edward the First) assigned to the royal touch a place midway between the polypharmacy of the physician and the craft of the surgeon—"a delicate provision," says Dr. Crawfurd, "for the contingency of the king's therapeutical impotence." As this passage is almost the only original suggestion in his "Rosa Anglica," we may guess that John, like the many persons who do not know that they are humorists, was naïvely unaware of his own scepticism. It is a happy biographical trait of Henry of Navarre that, at Ivry, on cutting down a man with his sabre, he exclaimed, "Je te touche, que Dieu te guérisse." But perhaps this says less for Henry's scepticism than Dr. Crawfurd thinks, characteristic of him as the story is. Even in the sixteenth century the stronger the creed the safer to jest with it; the Church has always tolerated the jester, while handing over the wrangler to the secular arm.

The first great sceptic, to whose robust disdain of this item of his divinity the discredit of the touch is due, was William the Third. His sturdiness did him the more honour as such a proof of his dynastic authenticity would have been convenient. This testimony had more weight with Anne; though it would have gone hard with her heirship had it depended on her cure of Samuel Johnson. The gold touch-piece she bestowed upon her eminent patient is, we are told, in the British Museum. It is hard to believe that such great modern surgeons as Alibert and Dupuytren presented sufferers from the evil to Charles the Tenth; perhaps they were the last medical authorities to be so complaisant; though the later Stuarts amused themselves, and others, by clinging to this last rag of their divinity until their dissolution.

I hope my readers will agree with me that I have taken no improper liberty with them in dwelling at this length upon so able and entertaining a volume.

CLIFFORD ALLBUTT.

GROUP-THEORY.

Theory of Groups of Finite Order. By Prof. W. Burnside, F.R.S. Second edition. Pp. xxiv+512. (Cambridge: University Press, 1911.) Price 15s. net.

IN the new edition of Prof. Burnside's standard work important changes have been made by rearrangement of old material, and by addition of new. The main feature, for which many English readers will be very grateful, is the addition of several chapters on groups of linear substitutions. Among the most important of all contributions to group-theory must be reckoned the memoirs of Frobenius in the Berlin *Sitzungsberichte*; unfortunately they are not very accessible to English students, and are by no means easy to read; hence, Prof. Burnside's connected, and in many ways independent, discussion of this part of the theory is very welcome. In particular, there is a chapter on characteristics, and another on various special applications; it may be noticed, as showing the power and value of the characteristic-theory, that the theorem "every group whose order contains only two distinct primes is soluble," appears as a corollary.

At present, the theory of groups is in a very interesting state for various independent reasons. Several great mathematical theories are intimately associated with group-theory, or at least with some aspect of it; thus, there is the theory of algebraic equations, the division of period and argument in elliptic functions, and the immense field of elliptic modular functions—to mention these alone. But, besides this, the theory of groups, which so long seemed a rather arid appendix to the theory of permutations and combinations, has changed its aspect into a definite, independent, and fascinating branch of analysis, as peculiar and baffling as the theory of numbers, if not more so. It has now been approached and studied under four, at least, of its Protean aspects; as defined, in the abstract, by a multiplication-table, or, equivalently, by a set of formal equations like $a^2=b^2=(ab)^2=1$; as a set of permutations; as a set of linear substitutions; and as a set of geometrical operations. Each of these methods has suggested intrinsic properties of groups, and we have now a considerable set of distinctive epithets, such as "self-conjugate," "Abelian," "metabelian," "soluble," and so on, each of which marks a definite advance in classification. But some of the most obvious problems seem as far from solution as ever; for instance, it seems probable that no group of odd order, except a cyclical one, can be simple, but the proof has still to be found.

There is, therefore, abundant field for research, and the more varied the interests and attainments of those who undertake it the better, because some new symbolism, or some new association with geometry, or the like, may lead to the discovery of new properties

of groups. Oddly enough, on the other hand, group-theory assumes less preliminary knowledge than anything else except arithmetic, so that beginners, in a sense, start level, and have equal chances for a prize. Many of Prof. Burnside's examples, and, in particular, the notes at the end of the volume, are intended to suggest various lines of research.

It has already been observed that some of the matter of the first edition has been rearranged. The general effect has been to put more of the abstract theory in the earlier chapters; this will probably commend itself to experts, but will not make the book easier for beginners. They will probably find it convenient to pick and choose, and pay special attention to examples; they might begin by reading chaps. i.–v., vii.–ix., xviii.–xx., passing lightly over the more difficult parts; they must, in any case, become quite familiar with transformation, conjugate and self-conjugate operations and sub-groups, and the meaning of Hölder's symbol G/H. The great landmarks in the less advanced part of the theory are the properties of composition-series and their allies, together with Sylow's theorem and its consequences; these, at any rate, must be fully mastered before trying to advance.

The English student of group-theory is now fortunate in having at his disposal three excellent text-books in his own language: Mr. Hilton's "Finite Groups," which is a capital introduction to the subject, with plenty of easy examples; the present volume; and Prof. Dickson's "Linear Groups," which is particularly valuable for its completeness of detail, and its analysis of Galois fields. Our younger mathematicians are now fairly free from the shackles of ancient tradition, and we may confidently hope that some of them will add to our knowledge of this fascinating theory.

G. B. M.

A GUIDE-BOOK FOR INDIA.

A Handbook for Travellers in India, Burma, and Ceylon, including the Provinces of Bengal, Bombay, Madras, the United Provinces of Agra and Lucknow, the Panjab, Eastern Bengal and Assam, the North-West Frontier Province, Baluchistan, and the Central Provinces, and the Native States of Rajputana, Central India, Kashmir, Hyderabad, Mysore, &c. Eighth edition, with 80 maps and plans. Pp. cxvi+530. (London: J. Murray; Calcutta: Thacker, Spink, and Co., 1911.) Price 20*s.* net.

THE handbook to India, Burma, and Ceylon issued by Mr. John Murray, which now appears in its eighth edition, has reached its present form after a long series of revisions. It was first published between 1859 and 1883 in four volumes, and was the work of a well-known Oriental scholar, the late Captain E. B. Eastwick, who collected the material during several journeys to India. When we remember that in the period immediately following the Mutiny of 1857 communications throughout the Empire were imperfect, and that the present vast library of Indian books of reference, such as the imperial and provincial gazetteers, the census, archæological, and other departmental reports were not available for reference, Captain Eastwick's work was, in its way, admirable. Since the book appeared in its original form it has been subjected to constant revision by competent scholars, and has now been practically rewritten by Mr. H. C. Fanshawe, late secretary to the Government of the Panjab, and author of an excellent account of the imperial city of Delhi. The arrangement has been recast in accordance with the most recent railway developments, and the accounts of the most important places have been revised in the light of modern research.

The handbook in its present form thus furnishes a compendium of the most trustworthy information regarding the topography, races, antiquities, and modern history of the Empire. As might have been expected, there are in some places signs that the new material has been imperfectly assimilated with the old, and some errors, misprints, and omissions have escaped the attention of the latest editor. Thus, Sir Colin Campbell's force at the final relief of Lucknow, which consisted of seventeen battalions of infantry, twenty-nine squadrons of cavalry, and 134 guns, certainly aggregated more than 2000 men; the venerable error that the River Gumti, really the Gomati, "rich in cows," means "serpentine," should not have been repeated; the sportsman might have been warned that rifles carrying the army cartridges are rigidly excluded, and he should have been advised to supplement his Express rifle by a smaller bore, high-velocity weapon.

These, however, are trifling matters, and the introductory chapter which gives advice on expenses, clothing, food, sanitation, and camping represents the accumulated experience of many competent authorities, while the accounts of the great cities, their architecture and industries, the campaigns and battles, leave little to be desired. The maps and plans are numerous, and, as a rule, excellent. The present edition, while it will be indispensable to the tourist, will find a wider circle of readers among officers on Indian service and their friends at home who are interested in the country and its people. For ordinary people it will be a useful substitute for a collection of the more bulky books of reference, such as the imperial and provincial gazetteers and the departmental reports, which must be consulted by all serious students of the Indian Empire, its races, and their history.

ENGINEERING GEOLOGY.

Geology for Engineers. By Lieut.-Colonel R. F. Sorsbie, R.E. Pp. xxvii+423. (London: C. Griffin and Co., Ltd., 1911.) Price 10*s.* 6*d.* net.

ONE important engineering lesson from this book is the danger of working with unknown materials and of using unfamiliar terms. The book is a compilation, mainly from second-hand sources of information, half of which are out of date. The author has seldom discovered the recent original authorities. The work consists of two parts; the first 238 pages

summarise the rudiments of general geology; the special subject of the book is confined to the second section of 160 pages.

The first part is unduly long, and is so inaccurate and out of date that engineering students will be well advised to learn the elements of geology from a more trustworthy text-book. The author's petrological knowledge may be illustrated by the following examples. "Peridotite.—A name used for a basalt or dolerite rich in olivine, chiefly noticeable on their [*sic*] alteration into serpentine" (p. 111). Clay (p. 114) is said to have "very nearly the same composition as the mineral felspar." The Silurian greywackes are included on p. 281 in the crystalline schists. Oolite is described as composed of "egg-like granules." The definition of agglomerate omits the essential character of the size of the fragments. In the author's definition of conglomerate, puddingstone is based on the rounded form of the pebbles instead of on the induration of the rock. The trap-rocks are retained in reliance on authors who, in this respect, were conservative when they wrote in 1885. The table of rock characters on pp. 203 to 206 is useless and misleading.

The section on palæontology is better, as it is briefer; it is equally inaccurate. The author says that the Cœlenterata are characterised by "a distinct body-cavity," and he refers to Favosites, which he includes in the Hexacoralla, as having septa "in sixes." On an authority of 1889 he states (p. 153) that the Radiolaria "are rarely found fossil."

In the chapters on stratigraphy are included various tables of foreign formations. Those for Australia, New Zealand, and South Africa are quoted from Prestwich's "Geology" of 1886. They are only of historic value. The value of the information on British stratigraphy may be judged from the statement (p. 180) that the Calciferous sandstones are overlain by the Carboniferous limestone in the north of Scotland.

It may be claimed that the book should be judged by its second part, which is, however, no better than the first. It contains much useful information, but most of the authorities quoted are out of date, and inadequate knowledge of geology and geography has led the author into many mistakes. He assures us (pp 239–40) that in open and barren plains

"the construction of railways influences the rainful [*sic*] to a very great extent. Instead of continuous drought all along the Pacific railroad, rain now falls in refreshing abundance."

The authority quoted for this extinct belief is Humber's "Water Supply of Cities and Towns," published in 1876. This book is the author's most oft-quoted source of information on matters connected with rainfall. The rate of deep-sea sedimentation is adopted, at second hand, from "the late Mr. Tylor" (p. 383), though a later authority on this question is elsewhere referred to (p. 23) as "Mr. Murray." The author often refers to himself as the authority for his statements, and amongst other criteria of doubtful geological value, which he advances as a result of his own observations, is that "snakes are common on light soils."

AN EASTERN HORSE-BOOK.

The Faras-Nāma-e Rangīn; or, the Book of the Horse. By "Rangīn." Translated from the Urdu by Lieut.-Colonel D. C. Phillott. Pp. xx+85. (London: Bernard Quaritch, 1911.) Price 10s. 6d. net.

THE author of this treatise, who wrote under the *nom de plume* of "Rangīn," was, it appears, from the translator's introduction, one Sa'adat Yar Khan, whose birthplace was Delhi. After serving for some time in the cavalry of one or more of the native princes, he eventually became a recluse, during which period of his life he appears to have written the present and other works. He died in October, 1835. In the East the "Fars-Nāma" rapidly attained popularity, as is attested by the fact of its having passed through several editions; but we fear that the same good fortune is unlikely to attend the translation. Indeed, it is difficult to see to what class of readers it is likely to appeal in this country, although it is suggested by the translator that it may prove of service to officers of native cavalry in India. Personally, we should have thought a good English work on the management and disease of horses would have suited their purpose far better, except perhaps as regards native ideas of the "points" of a horse.

In the introduction, Colonel Phillott, after referring to the important part played by the horse in the history of civilisation in India, observes that no treatise on the subject would be complete without mention of the legends and myths connected with its origin. These differ markedly according as to whether they are derived from Moslem or Hindu sources, although, as is so often the case in similar matters in India, some of these show evident signs of a mixed origin. As "Rangin" was a Moslem, he naturally wrote from the point of view of his own creed, and the translator has accordingly considered it desirable to give an account of the Hindu belief on this subject. As bearing on the origin of the classical myth of Pegasus, it is interesting to note that "according to Hindu legends, the horse was created a flying animal, one that could fly and run, and no man or God could snare it. Indra wanted horses for his chariots, and requested the sage Salihotra to deprive the horses of their wings. Accordingly Salihotra, by his *yoga* or supernatural power, derived by his austerities, accomplished Indra's wish." Deprived of their power of making long journeys in the air in search of medicinal herbs, the horses asked Salihotra to write a book on their diseases, which he did, and in time the Sanskrit name of the writer came to mean, first veterinary science, and then a horse. To this day native cavalry regiments have their *salotris*.

In connection with native horses, Colonel Phillott mentions that

"Indian countrybreds will eat and thrive on food that would probably kill English horses. In the Persian Gulf and elsewhere locusts, fish, and dates are regarded as legitimate food for horses and cattle; in Tibet the *tanghans* [horses] are given pig's blood and raw liver; and in the cold regions of Central Asia meat is regarded as a necessity for horses."

The actual text of the work must be passed over with the bare remark that "Rangīn" appears to have acquired a considerable knowledge of equine anatomy, both normal and pathological.

R. L.

ANIMAL PSYCHOLOGY.

La Nouvelle Psychologie Animale. By G. Bohn. Pp. ii+200. (Paris: F. Alcan, 1911.) Price 2.50 francs.

Clever Hans (the Horse of Mr. Van Osten): a Contribution to Experimental Animal and Human Psychology. By Oskar Pfungst. With an introduction by Prof. C. Stumpf. Translated from the German by Carl L. Hahn. With a prefatory note by J. R. Angell. Pp. vii+274. (New York: H. Holt and Co., 1911.) Price 1.50 dollars net.

DR. BOHN'S book is, as he himself states in his preface, the sequel and complement of an earlier work, "La Naissance de l'Intelligence," already reviewed in the pages of this journal. Its aim is to present a concise account of the development of psychism in the comparatively high forms of life represented by the class of anthropods and vertebrates respectively. The vital activities of the lower organisms are not neglected, however, and in the opening pages of the book one finds an excellent summary of the forms of explanation in terms of physical chemistry which Prof. Loeb has made famous under the names "tropisms" and "differential sensibility."

Dr. Bohn is Loeb's most distinguished follower, and he has defined the above-mentioned terms and indicated exactly to what forms of behaviour they are applicable with a brilliance even superior to that of the master himself. There is little doubt that the terms have been used with great laxity by many writers, particularly by those psychologists who are inclined to reject Prof. Loeb's views, and Dr. Bohn has done a real service to science in rendering them precise. Moreover, no one unhampered by preconceived theories will find fault, on the score of method, with Dr. Bohn for endeavouring to apply the law of parsimony as rigidly as possible, and only appealing to psychical factors after all the possibilities of physical and chemical explanation have been exhausted. Yet the result may not be entirely convincing, for although the observation of lowly forms of life encourages a mechanical system of explanation which the man of science is then stimulated to develop with ever-increasing complexity until it seems to give an approximately accurate account of even the higher forms of conscious behaviour of highly developed organisms, an investigator starting from the other end of the scale and acquiring an intimate knowledge of the nature and significance of consciousness in the life of man and the higher animals is likely to come to a very different conclusion as to the nature of, say, even protozoan activity. It seems, indeed, inevitable that there should be at least two widely diverging schools of thought in animal psychology, out of the conflict of the views of which truth will ultimately emerge, and that both are therefore necessary to the science.

Dr. Bohn passes on to a clear statement of the meaning and sphere of influence of "associative memory," and after a full discussion of the principal instincts of "articulated" animals, in which he shows that the word "instinct" explains nothing, and that the so-called instincts are aggregates of diverse activities which are far from exhibiting the exact adjustment to one another and to the environment with which they have been hitherto credited, he describes the principal experimental methods employed in the investigation of the psychical activity of the vertebrates, together with the more important results of these investigations. The little book is crammed with the most valuable material, set out in the most concise and attractive style, and one is glad to note that it has been crowned by the Academy of Moral and Political Sciences. No psychologist should omit to read it and re-read it.

"Clever Hans" was a Russian trotting horse, who took German music-hall audiences by storm by his remarkable power of working simple arithmetical sums, and answering other questions requiring a similar kind of reasoning ability. The owner, an elementary-school master, had taken him when young and taught him the rules of arithmetic according to the ordinary approved methods, and was himself convinced of his *bona fides*. An unofficially appointed Commission of psychological experts eventually proved conclusively, by experiments with the animal, that no true reasoning processes were performed, but that the horse, who tapped out its answers with its right foreleg, judged, by minimal muscular movements unconsciously performed by the questioner, when it had to stop. The questioner in asking the question was found to bend slightly forward, and then unconsciously straighten himself when the correct number of taps had been given. A slouch hat improved the "scores" by magnifying the amplitude of the movements, and when the questioner himself did not know the answer the horse was quite unable to give it. For further details of this most entrancing story, the reader is referred to the book itself.

WILLIAM BROWN.

OUR BOOK SHELF.

Vine-growing in England. By H. M. Tod. Pp. x+113. (London: Chatto and Windus, 1911.) Price 1s. net.

THE vision of the British householder sitting under his own vine seems capable of being realised from the perusal of Mr. Tod's interesting little treatise on vine-growing in England. The author examines the historical evidence connected with the vine in England and points out conclusively that its culture was once widespread not only in the country but also in and around London. Its decline no doubt was largely brought about by the dissolution of the monasteries, and it is also suggested that the enclosure of the land rendered many situations unsuitable for vineyards. The practical details for successful viticulture given in this book are admirable, and the author speaks with authority gained from a wide experience of vine growing in England, Europe, and South Africa.

Anyone anxious to start vines either in the open or against walls will find in the book before us almost every detail set out and every question answered. The site for the vineyard and the nature of the soil are

naturally of prime importance. The ground should slope both eastwards and southwards, and should be sheltered from south-west winds. The land should not be rich, but it must be well drained, and a point of interest in this connection is that vines can be grown for profit on poor land which is not suitable for corn.

Five years must elapse before the vines may be allowed to begin to bear, and the crops at first must be small, so that anyone who intends to lay down a vineyard will have to be prepared to wait for his profits. During the five years of waiting and after the vines will require much careful attention.

At the end of the book there is a chapter on wine, but it is a matter for regret that nothing of a practical nature is said about wine-making in England, though it is true that allusion is made to good wines which have been produced in this country, nor of the possibilities of profit of a wine industry. A list of the best vines for growing in England is given, with short accounts of the grapes and of the purposes for which they are most suitable.

Further Researches into Induced Cell-reproduction and Cancer. Consisting of papers by H. C. Ross, J. W. Cropper, and E. H. Ross. (The McFadden Researches.) Pp. 63. (London: John Murray, 1911.) Price 3s. 6d. net.

IN this little book Mr. H. C. Ross gives a number of papers by his colleagues and himself on the lines already laid down in the larger book which appeared earlier in the year. Much enthusiastic work is indicated, but it is difficult to realise that the booklet is intended as a serious contribution to science. The same criticisms that were levelled at the earlier production can be urged with equal or even greater cogency against this recent production, and it is really very difficult to avoid the conviction that the collaborators are gaily prancing about on dangerous ground the nature of which they very imperfectly comprehend. Thus the description of centrosomes and the familiar structure of erythrocytes is possibly a correct portrayal of appearances seen, but the conclusions as to the inducement of division in them are absolutely unconvincing. That there may be disruption is probable enough under the conditions employed, but the case for a true division in the sense in which this is ordinarily understood does not appear to have been made out in the examples they describe. There is, furthermore, an absence of anything like a cautious and critical attitude towards the surprising results alleged to have been obtained, and this of itself is enough to arouse scepticism in the mind of anyone who has had any experience of the pitfalls that lie in the path of all scientific investigation, and these pitfalls are especially numerous in the field of cytology.

The Adventures of Jack Rabbit. By Richard Kearton. With eight autochromes and numerous photographs direct from nature by Richard and Grace Kearton. Pp. xii+248. (London: Cassell and Co., Ltd., 1911.) Price 6s.

ALTHOUGH animal autobiographies do not appeal to ourselves, Mr. Kearton's attempt to describe the life and experiences of a wild rabbit will probably prove acceptable to a number of juvenile readers, especially during the Christmas holiday season; and if its perusal results in even a few of such readers taking seriously to nature-study the writer will doubtless have succeeded in his aim.

The feature of the work in which adults will be interested is formed by the illustrations, many of which, we think, are even above Mr. Kearton's high average; among these special attention may be directed to the eight "autochromes," by which we presume are meant colour-photographs. These are absolutely superb, whether they take the form of a clump of bluebells or a mass of blue speedwell, or whether they depict animals. Among those of the latter type, we are more particularly pleased with the portrait of a young fieldfare, and the picture of a thrush's nest and eggs amid their surroundings. It is, however, noteworthy in the case of the latter that the nest, eggs, and supporting stems are much more conspicuous than they would be in nature; this, we presume, being one of the unavoidable defects of colour-photography. The illustrations alone are quite sufficient to sell the book.

As regards the text, it may be remarked that it is unnecessary to refer to the thrush as the "song-thrush," a prefix, in this and other cases, being required only for species other than the typical one. It would also be better to call such animals as the water-rat and the field-mouse by their vernacular names instead of alluding to them as "voles." R. L.

The Natural History and Antiquities of Selborne. By Gilbert White. With illustrations in colour by G. E. Collins. Pp. viii+475. (London: Macmillan and Co., Ltd., 1911.) Price 10s. 6d. net.

SEVERAL years ago Mr. E. A. Martin, in "A Bibliography of Gilbert White," gave the results of an inquiry as to the number of editions which had been published of the famous "Natural History of Selborne." It appeared that up to the end of 1895 no fewer than seventy-three separate editions of the work had been issued since the original handsome quarto was published in 1789; and this number is now probably well above one hundred. There is apparently a constant demand for copies of Gilbert White's classic, and it is satisfactory that this should be so, for no more inspiring work on natural history has ever been written.

As good wine needs no bush, so White's "Selborne" requires no explanatory notes, and is best left to speak for itself. The present edition is free from editorial interference, its distinguishing characteristic being the twenty-four coloured plates representing outdoor life and scenes in and near Selborne. In the selection of subjects and their treatment the artist has shown sympathetic feeling and execution which are as rare as they are welcome. The result is a beautiful edition of a work which should be in every library. The text is ever fresh, and it would be difficult to produce more delightful illustrations to it than those painted by Mr. Collins.

A Primer of Astronomy. By Sir Robert Ball, F.R.S. Pp. viii+228+11 plates. (Cambridge University Press, 1911.) Price 1s. 6d. net.

THE first edition of this book was published in 1900, and there was a reprint in 1906. To the present issue two large charts of the northern and southern celestial hemispheres have been added, and also a chapter of forty-two pages, entitled "Celestial Objects." By means of these additions, the reader will be able easily to find his way about the heavens and identify objects and scenes of particular interest. It is a little to be regretted that the text has apparently been unaltered with the view of bringing it up to date; for though the fundamental facts relating to the solar and stellar systems remain much as they were when the book was written, a few statements, such as that, for instance, referring to Halley's comet as "due again about 1910," are—to say the least—anachronistic. We hope that the demand for the book will be great enough to justify the publication of a revised edition at no distant date.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Weather of 1911.

WITH reference to Sir Edward Fry's letter in NATURE of November 16, the following figures may be of interest.

We have some eighteen records of the temperature up to a height of 15 kilometres or more over the British Isles during the period of the hot weather, distributed over seven days. Excluding the records for Scotland in September, where the weather was not hot, the following departures from the mean are found:—

At 2·5 kilometres a temperature of	+5·5° C.
5·0 ,, ,, ,,	+2·5°
7·5 ,, ,, ,,	normal
10·0 ,, ,, ,,	normal
12·5 ,, ,, ,,	−7·0°
15·0 ,, ,, ,,	−5·0°

These figures show that the heat was confined to the lower strata. With anticyclonic weather, such as prevailed during the summer, it is usual to find a negative departure from the mean temperature above 12 km.; but the greatest departure from the mean is generally found at about 7·5 km., where, as a rule, we get +5° C. The +5° C. at 2·5 and the normal value at 7·5 are very unusual, but they are shown more or less in every record.

I agree with Dr. Shaw in thinking that the surface conditions are imposed upon us by the conditions that prevail above. From the total and partial correlation coefficients that I have obtained it seems to me that the pressure in the layers of air just under the isothermal, which may be taken as the pressure at 9 km., is the dominant factor in the distribution of pressure and temperature in the whole region of the atmosphere that has been explored, with the exception of the temperature near the ground, which in temperate latitudes is certainly more dependent upon the direction of the wind than upon anything else.

I do not altogether agree with Dr. Shaw in thinking that the changes of temperature at 9 km. are in any way due to changes in the direction of the wind at that height. It seems to me more likely that they are produced by rising or falling air, and that the vertical motion, and therefore the temperature, is the direct result of the variations of pressure.

Unfortunately, it is only on rare occasions that we can ascertain the rate and direction of the wind at great heights; but there is sufficient information to show us whether the temperature at any given height up to 15 or 20 km. is dependent upon the direction and rate of drift of the atmosphere as a whole, for the direction and distance of the falling place of the balloon supply the requisite information about the general drift on any particular occasion.

I hope shortly to tabulate the results of some 200 ascents, and ascertain what the connection, if any, may be.

Pyrton Hill, December 2. W. H. DINES.

The Interaction between Passing Ships.

THE statement made in NATURE of November 30, in the article on "The Interaction between Passing Ships," to the effect that no experiments have been made to test this interference in shallow water except those recently carried out at Teddington, needs some little qualification. A somewhat extensive set of experiments to test this, among other points, was carried out some two months ago at University College, Dundee. Screw-propelled models of various sizes, at distances apart up to 200 yards, were used in these experiments, the depth of water varying from 1·6 times the draught of the vessels to 12 times the draught. The results were of such apparent interest that they were communicated to the Admiralty, who arranged for the Teddington tests, of a more restricted nature, to be carried out on larger accurate scale models of the *Hawke* and *Olympic*. The results of the Dundee experiments have been for some weeks in the hands of one of the scientific societies, and it is hoped that they may soon be made public. A. H. GIBSON.

Engineering Department, University College, Dundee, December 2.

December Meteor-showers.

THE following meteor-showers become due during the period December 8–31:—

Epoch December 7, 17h. (G.M.T.), second order of magnitude. Principal maximum, December 8, 8h. 15m.; secondary maximum, December 8, 3h. 40m.

Epoch December 7, 22h. 30m., approximately sixth order of magnitude. Principal maximum, December 8, 1h. 30m.; secondary maximum, December 9, 1h. 40m.

Epoch December 13, 17h. 30m., approximately sixth order of magnitude. Principal maximum, December 12, 1h.; secondary maxima, December 11, 15h. 30m., and December 13, 11h.

Epoch December 13, 13h. 30m., thirteenth order of magnitude. Principal maximum, December 14, 22h. 5m.; secondary maxima, December 13, 21h. 5m., and December 16, 17h. 30m.

Epoch December 18, 2h. 30m., thirty-fifth order of magnitude. Principal maximum, December 18, 19h. 50m.; secondary maximum, December 19, 7h. 40m.

Epoch December 19, 10h., approximately fifteenth order of magnitude. Principal maximum, December 19, 13h. 50m.; secondary maximum, December 19, 17h. 15m.

Epoch December 22, 1h., fourth order of magnitude. Principal maximum, December 23, 0h. 40m.; secondary maximum, December 22, 21h. 30m.

Epoch December 23, 2h. 30m., ninth order of magnitude. Principal maximum, December 24, 6h. 30m.; secondary maximum, December 24, 18h. 15m.

Epoch December 25, 15h. 30m., approximately twentieth order of magnitude. Principal maximum, December 27, 13h. 50m.; secondary maximum, December 26, 15h.

Epoch December 30, 0h. 30m., approximately eighteenth order of magnitude. Principal maximum, December 31, 15h.; secondary maxima, December 31, 11h. 30m. and 16h. 15m.

There are reasons for believing that the total mass of a meteoric maximum may be considerably greater than is generally supposed. Such a mass of matter, in being brought to rest, must give rise to currents in the upper strata of the atmosphere, these currents very probably constituting what may be known as atmospheric depressions, inasmuch as a column of air if thus set in motion will weigh less than when undisturbed.

In December meteor-showers are more evenly distributed over the month than was the case in November; still, there are periods of special meteoric activity. The first of these, in intensity as well as in time, occurs on December 8; the second period, as regards intensity, is spread over the days December 22–24; while the third period, which is comparatively weak, falls between December 16 and 21. Shooting stars may be numerous on the night of December 31. JOHN R. HENRY.

Dublin, December 4.

The Inheritance of Mental Characters.

To Dr. Archdall Reid it is an "astounding thing" that I should imagine that Prof. Pearson could possibly agree with the interpretation I ventured to put upon his statement which Dr. Reid condemns as "void of all content" and "quite nonsensical." Dr. Reid evidently feels that my quotation from his attack upon Prof. Pearson was not quite fair, in that I omitted part of the context which he regards as essential. I apologise for an entirely unintentional and unforeseen cause of offence. As he has himself rectified this omission, I may, I presume, take it that all is *en évidence*

requisite to substantiate his wholesale and unqualified condemnation. May I follow Dr. Reid's example, and quote the whole of his quotation from Prof. Pearson?—"The sameness [in the appearance of moral and intellectual faculties as well as of physical characters][1] surely involves something additional. It involves a like heritage from parents. The degree of resemblance between children and parents for the physical characters in man may be applied to the degree of resemblance between children and parents for psychical characters. We inherit our parents' tempers, our parents' consciousness, shyness and ability, even as we inherit their stature, forearm, and span." This is the whole of the statement condemned.

I gather that Dr. Reid thinks as I do, that individuals vary in their capacity for developing various mental characters such as temper, skill in mathematics, music, and the various uses of language, and that such capacities may be, and very frequently are, inherited. Physical characters, different from "eye-colour or hair texture," but such as the capacity for a high or low degree of development of the muscles, bones, or internal organs, and including "stature, fore-arm, and span" to a considerable extent, also vary, and are very frequently inherited. Such characters, mental or physical, depend upon both inborn capacity and environment for development. Both capacity for development and environment vary, but only the capacity for development is inherited. Therefore I see nothing in Prof. Pearson's statement which in any way warrants Dr. Reid in saying that it is "utterly without significance, utterly void of all content," and "is so vague as to be quite nonsensical."

It is quite evident that Dr. Reid believes that Prof. Pearson holds that something beyond a capacity for development, which varies in individuals, is inherited. But there is nothing in the statement which implies anything of the kind, so it appears that Dr. Reid has issued an unqualified condemnation of something, with which he does not disagree, that Prof. Pearson has said, because he does not agree with what he believes Prof. Pearson thinks but has not said.

Now I know that there are people who claim the peculiar power of knowing what others think without using any of the usual physical means of communication. I, unfortunately, have no such power, and I take it that there are many who, like myself, are in a less fortunate position than the members of Dr. Reid's audience, in whose minds, he tells us, no misapprehension as to his meaning arose. The unfortunate persons who have no means, beyond reading what has been written, of knowing what Prof. Pearson and Dr. Reid think, are liable to be seriously misled by what Dr. Reid wrote in his paper. In his anxiety to emphasise the great capacity possessed by man for making acquirements, Dr. Reid runs perilously near to ignoring the facts that this general capacity is made up of many capacities, that all these capacities are variable, and that the variations are heritable. Is he so annoyed with Prof. Pearson for laying what he considers undue stress upon the heritable part of mental characters, that his criticism has gone beyond what he actually means? This is suggested by the manner in which he treats some of the physical characters in his paper. "Heads, hearts, lungs, livers, and the like are inborn and invariably present in parents, and offspring." Certainly, but the capacity for development varies in different individuals and is heritable. For instance, the heart of one individual will react to frequently repeated and violent exercise by increased muscular development, while in another it will give way and dilate under precisely similar conditions. So also with mental characters. No environment will make some men mathematicians, while others will become great mathematicians in a comparatively unfavourable environment. Much the same may be said of temper and similar characters.

After all, it is surely the heritable part—the variations in capacities for making acquirements in various directions—that really matters from the eugenic point of view.

Dr. Reid fears that "Prof. Pearson will pray ardently to be delivered from his friends." Unfortunately I have not the slightest claim to the friendship of Prof. Pearson. I neither fear nor hope with regard to his feelings as to what I have written about his statement. Even should he publish a repudiation of my interpretation in every detail, my position would be precisely what it is now—one of protest against a wholesale, unqualified, and one might almost say violent condemnation without any very evident reason, a condemnation likely to cause misunderstandings in a subject in which I am particularly interested. Such methods in controversy can serve no useful purpose.

Glasgow, December 2. CHARLES WALKER.

[1] Inserted to make the meaning of the context clear.

On the Occurrence of Brown Cannel Coal ("Kerosene Shale") with *Reinschia australis* in the Falkland Islands.

AMONGST an interesting exchange series of fossils sent to the National Museum, Melbourne, by the honorary curator of the Falkland Islands Museum, there is a specimen of "kerosene shale," which, on account of its deep brown colour, resinous lustre, and eminent conchoidal fracture, at once reminded me of the oil-bearing rock of Hartley, New South Wales. Upon slicing this specimen and comparing the structure with a slide of the Hartley rock in our museum cabinet it was evident that they were practically identical. The Falkland Islands specimen is formed, like that of the New South Wales rock, almost entirely of the small (?) thallophyte described by MM. Renault and Bertrand under the name of *Reinschia australis*, and believed by them to be nearly related to the Hydrodictyaceæ or Volvocineæ. The deep yellow coloured sacs are of the same dimensions in both examples. The specific gravities of the Falkland Islands and the New South Wales rocks were found to be approximately equal, being in both cases slightly more than 1. Prof. Liversidge gives that of the Hartley, New South Wales, specimen as 1·052. As Liversidge points out, this rock is scarcely a shale, since the shaly structure in hand-specimens is absent, but would be more aptly termed a "Cannel coal," or, as suggested by the Rev. W. B. Clarke, "brown cannel."

The Falkland Islands specimen was found near Hill Cove, West Falkland, and I have since been kindly furnished with further information as to its occurring a fair distance up several river valleys; so that this fact, together with its tolerably fresh appearance and only slightly water-worn surface, does not support the idea that it may be drifted from a great distance. There is considerable probability that deposits of this "kerosene shale" will eventually be found *in situ*, since the fact of a typical Glossopteris flora occurring in East Falkland has already been proved by J. Halle, the geologist to the Swedish Magellanic Expedition (*Geol. Mag.*, 1908, p. 265). To quote that author's own words:—"Fossils, principally leaves of Glossopteris, occur in many places, and it is evident that the whole southern part of East Falkland south of Wickham Heights belongs to the Gondwana system." Not only does the fossil flora correspond in this remarkable way with other areas of Gondwanaland, but amongst the brachiopods in the above collection several of the Spirifers bear a close resemblance to New South Wales species. FREDERICK CHAPMAN.

National Museum, Melbourne.

Optical Projection of Figures in Full Relief.

AT the recent Glasgow Exhibition an optical illusion was exhibited which showed very distinctly and daintily living human figures in full relief, standing upon a desk, on a scale of about 8 inches = 6 feet.

The production has caused much debate in private circles, and I write in the hope that someone may be able to inform me how it was produced.

I may say that the images were shown in ordinary electric light, and no optical apparatus of any description was visible.

Behind the figures the wall, which was at a distance of about 8 inches, was covered by what seemed an ordinary flowered tapestry.

The writer saw the same thing about seven years ago on the stage in Paris, and then, as now, the explanation eluded him and many of his friends. CURIOUS.

THE NEW BELL-PETTIGREW MUSEUM OF NATURAL HISTORY IN THE UNIVERSITY OF ST. ANDREWS.

THE comparatively few specimens of natural history in the olden time were stored in the Library of the University or in other rooms, and though Dr. McVicar, the first lecturer on the subject of natural history, commenced a new collection, about 1826, in the old dining hall of the United College, the results were small. It was not until 1838, the date of the foundation of the Literary and Philosophical Society, that Sir David Brewster pressed forward the formation of a museum for the University; indeed, this was one of the main aims of the society. Under the fostering care of the distinguished principal just mentioned, active progress was made, and by and by the Government provided a hall and adjoining rooms, with the necessary cases for the collections. The specimens have gradually accumulated since that date, and to such a degree after 1882 that the crowded condition of the shelves renders the museum at present mainly a store for the preservation rather than the exhibition of its contents. The need for extension was felt as early as 1884, when the architect of the Board of Works made plans for the extension of the museum on the present site—plans which met with the approval of everyone in the University. These included an aquarium and a marine laboratory on the ground floor, laboratories and class-rooms over them, whilst another large hall and accessory rooms formed an extension of the present museum to Butts Wynd, these filling up the north-western corner of the quadrangle. Unfortunately, though sympathetic, Mr. Gladstone's Government could not afford the funds, and ever since the condition has been clamant. It is true the University might have provided the funds, for it has built large additions in the shape of new class-rooms and a physical laboratory, and appropriated 5000*l.* of the Carnegie grant for endowing the chemical research laboratory, the munificent gift of Prof. Purdie. The department of zoology, however, had to wait. Thus it happened that, after the death of Prof. Pettigrew, his widow resolved to erect a memorial to him in the form of the spacious new museum at the Bute Medical Buildings, a site which in itself is full of reminiscences of the long-continued efforts of the deceased professor and a colleague—supported by the late Lord Bute and the medical graduates of the University—for securing two *anni medici* at St. Andrews, the other three years being intended for Dundee. Moreover, as he was a former custodian of the old museum, the gift of this memorial of Prof. Pettigrew is peculiarly appropriate.

Accordingly, plans of the new museum were prepared by Messrs. James Gillespie and Scott, architects, St. Andrews (to whom this article owes its illustrations), and the negotiations between Mrs. Pettigrew and the University Court were energetically carried out by my colleague, Prof. Musgrove, who, indeed, superintended the operations from first to last. Now the entire structure has been completed and furnished with electric light, and the cases (jointly provided by Mrs. Pettigrew and the University) have been erected in the great hall, where the celebration banquet was held last September. These cases are of the most modern type, viz. of iron, each wall-case carrying a door composed of a single sheet of plate-glass 9 feet by 5 feet, larger

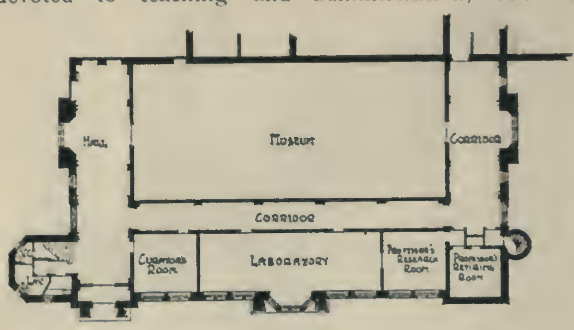
FIG. 1.—Front (West) of the New Bell-Pettigrew Museum.

sheets of glass occurring in the central cases on the floor.

The museum (Fig. 1) faces the west, close to the line of trees skirting the long walk of St. Mary's College, and is appended to the Bute Medical Buildings, from which access is gained by a fireproof door on each flat. Externally it has the botanic garden on three sides, and, when the approaches are widened, public access from Queen's Terrace and West Burn Lane will be facilitated; yet as regards position it is perhaps less in the current of visitors than the old museum in the United College.

The building (Fig. 1) is in the style of the English Renaissance, thus agreeing with the Bute Medical Buildings to which it is attached, and which were erected by Lord Bute, the same architects having prepared the plans. The main door faces the west and Queen's Gardens, and there are two stories. At each end of the roof is an open stonework canopy, the monogram of Prof. Pettigrew and his widow being engraved beneath.

The sunk floor contains long passages and spaces for storage and ventilation, and gives access to pipes and wires. The ground floor (Fig. 2) covers an area of about 130 feet by 75 feet, the entrance, already noted, being at the north-west corner, and leading to a vestibule, shut off by swinging and partially glazed doors, and a hall 65 feet long by 17 feet broad, with a spacious bow-window in the centre commanding views of the ancient halls of St. Mary's College and the principal's house, as well as the fine new Carnegie Library. At the eastern end of the hall are blank spaces which indicate where doors will in future open into a large lecture-theatre (not yet built). The ethnological collections will probably be placed in this hall. A stair leads from the north-western end of the hall to the upper floor, and in the spaces of the projecting tower are sinks and lavatories. The west front is devoted to teaching and administration, and is



-GROUND FLOOR PLAN-

FIG. 2.—For scale see Fig. 3.

separated by a long corridor from the main hall of the museum. It contains from north to south a curator's room, a class-room for practical zoology, 62 feet by 17 feet, a research-room, and a professor's room, near which is a turret-stair leading to the upper floor and to the roof. A corridor about 50 feet long and 17 feet broad extends along the southern face, with a spacious bow-window as in the north corridor; and as the botanical department adjoins and communicates with its eastern end, it is probable that this area will be devoted to the botanical collections.

The main hall of the museum on this floor is 90 feet long by 40 feet broad, and it passes upward to the roof, so that large skeletons, such as those of cetaceans, may be suspended in mid-air, rings and hooks being fixed to the beams, whilst a belt of wood below the cornice gives facilities for hanging pictures. The roof is doubly glazed, the inner layer being formed of muranese glass for diffusing the light, which is northern throughout, except at the lateral windows of the corridors. The floor is handsomely paved with marble mosaic, a special gift of Mrs. Pettigrew. This large hall will probably suffice for the mammals and birds, and, it may be, for the reptiles.

The upper floor (Fig. 3) has the same general area as the ground floor; but, since the great hall goes to the roof, only the western, northern, and southern galleries are available for cases. The spacious western gallery is about 122 feet long by 28 feet broad, and the inner borders of both it and the adjoining galleries are flanked by a series of Roman Doric columns, the effect of which is agreeable from all points of view. The entire upper floor is fireproof, being composed of iron and concrete with solid interlocked maple blocks. The north and south galleries are each about 70 feet long by 17 feet wide, a large bow-window occurring in the centre of each.

The extensive series of spirit preparations of the marine invertebrates (chiefly British), the collection of fishes and their eggs and early stages, will find space on the main part of this floor and along the northern corridor, but wall-cases are still required. Table-cases now in the old museum will occupy much of the floor. The southern corridor, which communicates by a door with the Bute Medical Buildings and is on a level with the department of geology, will probably contain the larger part of the geological and mineralogical specimens.

The munificence of Mrs. Pettigrew has thus solved the long-continued problem of museum accommodation, while at the same time it has produced a lasting memorial to a valued colleague, whose early researches on the muscular fibres and nerves of the mammalian heart, of the muscular fibres of the stomach and of the bladder, and whose ingenious ex-

-FIRST FLOOR PLAN-

FIG. 3.

periments on flight and animal locomotion are worthy of all praise. Indeed, as regards flight, it needed but a modern petrol engine to have raised Prof. Pettigrew's marvellous apparatus in the air, instead of flapping along the ground under the weight of a heavy steam-engine.

W. C. M.

THE PRESERVATION OF THE AFRICAN FAUNA AND ITS RELATION TO TROPICAL DISEASES.[1]

WHEN educated opinion in Europe, especially in England, could take stock of the ravages of British and Boer hunters who were exterminating the wonderful mammalian fauna of South Africa, a movement set in in the opposite direction for pleading with the British, German, French, and Belgian Governments to discourage or prohibit the destruction of wild life in their African territories. This desire to preserve the fascinating aspects of wild nature began to take a more acute shape in the last decade of the nineteenth century, and various African administrators, who were naturalists as well as sportsmen, induced their Governments to allow them to proclaim certain areas in Africa to be game reserves in which more or less complete protection was afforded to beasts, birds, and reptiles. The British

[1] "Further Correspondence Relating to the Preservation of Wild Animals in Africa." [Cd. 5775.] (H.M. Stationery Office.) Price 8½d.

Foreign Office took up the matter in the early 'nineties, and through Sir Clement Hill and others made arrangements with European nations for the institution of game regulations throughout Africa which might check the devastating raids of sportsmen. The movement was accentuated by a revelation of the wonders of the equatorial East African fauna, which really rivalled those of Cape Colony and Natal in the days of Roualeyn Gordon Cumming.

European opinion in Africa became sharply divided into two classes. There were the officials and some of the missionaries who, backed by the men of science of Europe, thought quite as much of the natural wonders of these African States, and regarded them as being an asset of equal importance with the profits which might be derived by the opening up of the country under the energy of European planters or capitalists. To some of us the lion, the elephant, the giraffe, the eland, kudu, sable antelope, and oryx were quite as important subjects of the new protectorates, and as deserving of reasonable protection, as the human inhabitants, and from an æsthetic point of view this argument was reasonable. On the other hand, the European immigrants and most of the natives clamoured for the right to destroy the wild game when and as they pleased. The Europeans, indeed, were seized by a kind of lust for blood which distracted them a good deal from the coffee, cotton, sugar cane, rubber, and tobacco planting which should have occupied most of their energies. They could not let an elephant or a buffalo, a rhinoceros or a giraffe, live within thirty miles of their station. The natives, forbidden to kill one another any longer, and unable to fight with the European, wished to devote their warlike enterprise to the destruction of big game, especially as the products of the chase were so marketable.

On the whole, the wishes of the official element, supported by the home Governments, prevailed. Game reserves were instituted, and to a great extent made valid by the application of laws. Highly-priced licences checked indiscriminate shooting on the part of Europeans, while the natives were seldom able to obtain arms of precision necessary to the rapid slaughter of game. So it was hoped in time a balance might be struck, and all the European possessions in Africa be studded with beautiful Government parks and paradises, in which would be preserved from extinction the wonderful fauna and the interesting flora of the most backward of the continents. In East Africa it seemed as if this policy of game preservation was a good one, even from a commercial point of view. The marvellous natural zoological gardens which it produced along the track of the Uganda railway brought every winter hundreds of well-to-do tourists, who spent much money in the country and amongst the natives. Then also it was thought that the African elephant might after all be harnessed to our industries, or allowed to breed as a provider of ivory; we might domesticate the eland and the bush-buck, and even do for the African buffalo what the European colonists of tropical Asia did for that of India several thousand years ago.

But at this stage—about three years ago—a new factor entered into the consideration of the problem. It was suspected that in many parts of Africa the existence of big game was actually prejudicial, and even dangerous, to the coexistence of the human race, black, white, or yellow. It seemed as though other creatures than man and monkeys must act as reservoirs of micro-organisms, especially trypanosomes, provocative of disease. Consequently, so long as they coexisted with man, the various species of tsetse-fly, of tick, and flea, would, even if infected human beings were isolated, have always the means of renewing their supplies of disease germs. In this way, epidemics of disease might be constantly renewed amongst man in Africa and his domestic animals. Certain game reserves, such as the elephant marsh in the southern part of Nyasaland, became peculiarly obnoxious to the European settlers round about. They stated that the herds of buffalo and other game that had increased and multiplied within this reserve were sources from which the tsetse-fly obtained at once its livelihood and its means of doing harm.

As regards the question of the relations between the tsetse-fly and the big game, it has been pointed out in a very authoritative manner by Sir Alfred Sharpe and other deservedly recognised authorities in the field that there are numerous districts in Africa almost entirely without big game which, nevertheless, swarm with tsetse-fly to such an extent that they are practically uninhabitable by man. In other words, that the existence of buffaloes, kudus, elands, zebras, &c., is *not* necessary to the perpetuation of the tsetse-fly, which apparently finds some other creature than these large mammals to supply it with the blood nutriment it requires or desires. Consequently, this argument does not hold as a justification for the extirpation of big game. Moreover, in many parts of West Africa where disease-conveying species of tsetse (Glossina) exist, there is very little big game. But within the last twelve months or so it has been proved conclusively by the biologists at work in Uganda that the large antelopes of that country are the hosts of dangerous trypanosomes, amongst others, of the trypanosome which causes sleeping sickness; and that if this terrible malady is to be extirpated from the Uganda Protectorate, practically all the larger antelopes must go; or at any rate, that their extirpation must be carried out rigorously in those well-wooded regions close to water inhabited by the dangerous *Glossina palpalis*.

Such discoveries, of course, have given great encouragement to that party among us specially represented by pioneers and colonists on the spot, eager for the unlimited destruction of wild life. There is, indeed, need for a wise administration of the law in this respect, and for the Colonial Office to obtain and to act on the most careful scientific advice. The same people that wish no check to be put on their blood-lust in regard to the destruction of rhinoceroses, of giraffes, of buffaloes and elephants, are equally eager to shoot all striking or beautiful birds, especially the various forms of white heron (egret) and crane—notably the crowned crane. Now it has been shown that certain forms of heron, especially the white ones, live almost entirely on insects and ticks, pursuing them by the waterside and attaching themselves to herds of domestic cattle or wild game, whom they relieve of their parasites and of the infesting flies. Similarly, crowned cranes, besides being very beautiful, are in every way the friend of man. They live chiefly on grasshoppers and locusts, they eat nothing that is of any value to man, and they are constantly at work destroying his enemies. In many regions of Africa the giraffe, the oryx, the elephant, rhinoceros, zebra, &c., are not in a position to be harbourers of trypanosomes, or if they are, these regions are entirely free from tsetse-flies.

The whole question is so important to the world in general, both for the extirpation of disease and the preservation of beauty and interest in fauna and flora, that it would be well to hold a Brussels Conference once in five years to discuss these questions, in regard to the destruction of harmful insects and the preservation or destruction of birds and beasts.

H. H. JOHNSTON.

CONCERNING CRUSTACEANS.[1]

THIS is a good instance of a sound type of book, one in which the specialist seeks to interest accessible outsiders in the particular class of animals to which he has devoted himself. It sometimes happens, indeed, that the specialist, forgetful that there was a time when even he knew nothing of his "ology," writes what no one outside the cult can pretend to enjoy or even to understand; or, having got narrowed down to a particular side of his subject, writes without perspective or any picturesqueness. But although Dr. Calman is one of the leading lights on crustaceans, and has by his researches made "carcinology" (we are instinctively sure that he hates the word) his lasting debtor, he condescends to write so that any fellow can understand, and he takes a broad view of his delightful subject. We say "delightful subject," not to depreciate the success which Dr. Calman has achieved in writing so interestingly about crustaceans, but because it must be admitted that there is considerable inequality in the literary value of the various classes of animals. Every zoologist for his own group, but there is no denying that crustaceans have more "points" about them than brachiopods, and more "habits" than crinoids.

FIG. 1.—A Spider-crab, *Maia squinado*, dressed in fragments of weeds. British (reduced). From "The Life of Crustacea."

Dr. Calman knows so much about crustaceans that he imbues even familiar themes with new interest. Thus the second introductory chapter, which gives an account of the lobster, as so many teachers of zoology do year after year, is enlivened by fresh touches. We read, for instance, of the prawn that was induced to put iron filings into its ears, with the result that its locomotion was seriously disturbed whenever a strong electro-magnet was brought into its vicinity. We are told, apropos of colour, that living lobsters are occasionally found of a brilliant red colour—ready boiled as it were. An account of the lobster's habits of food-testing, quoted from Dr. H. C. Williamson, strikes us as a fine piece of natural history. It seems, by the way, an unnecessary condescension to the laity to go on speaking of the gizzard as a stomach—a term which, as the author knows so well, is doubly misleading.

Helped by the excellent illustrations, the reader may, with a little care, get from the third chapter a grip of the somewhat intricate classification of the fairy-shrimps, water-fleas, carp-lice, barnacles, opossum-shrimps, wood-lice, sand-hoppers, prawns, squillas, lobsters, crabs, &c., that are all included under the title Crustacea. In the next chapter, which deals with life-histories, the author is careful to point out that while the occurrence of a nauplius larva in the life-history of, let us say, a branchiopod, a copepod, an ostracod, a barnacle, and a penæid prawn is strongly suggestive of the evolution-idea, there is no reason to entertain the idea that there ever was an ancestral type like a nauplius, or that any ancestors of the shore-crab resembled, even remotely, the zoëa stage with which the life-history of the individual now begins.

A great part of the book is devoted to a consideration of crustaceans in relation to their habitats, a mode of treatment which lays emphasis on adaptations. We are taken first to the sea-shore, where the "shifts for a living" are so numerous and varied. We read of symmetrical hermit-crabs in water-logged bamboo-stems; of crabs that masked themselves with seaweeds, and when placed in an aquarium among sponges picked off the weeds and put on sponge; of Prof. Garstang's observations on the breathing of Corystes when buried in the sand, of the ocypods that make a buzzing or hissing sound with their stridulating organ, perhaps, as Dr. Alcock suggested, to warn intruders that the burrow is already occupied; of the extraordinary protective resemblance of Huenia; of the bewildering variety of colour and colour pattern in Hippolyte; and so on through a wealth of fascinating illustrations. We are taken next to the deep sea, and the adaptations of long, stilt-like legs, of highly developed tactile organs, and the like are discussed. The discussion of luminescence is commendably cautious. Of a recently described case of certain deep-sea prawns which have photophores

FIG. 2.—A Deep-sea Hermit-crab, *Parapagurus pilosimanus*, sheltered by a colony of Epizoanthus. From deep water off the west of Ireland (slightly reduced). From "The Life of Crustacea."

[1] "The Life of Crustacea." By Dr. W. T. Calman. Pp. xvi+289. (London: Methuen and Co. Ltd., 1911.) Price 6s.

placed so as to illuminate the interior of the gill cavities, Dr. Calman well says: "What function they can discharge in this position seems beyond conjecture." It is very interesting also to read of *Platycuma holti*, which seems to feed on the deep-sea ooze, that it has a coiled food-canal, a very rare condition in Crustacea. Another kind of interest attaches to the occurrence of some old-fashioned types, such as the Eryonidea, in the great abysses. In an equally instructive manner the author deals with the crustaceans of the surface of the sea, of the fresh waters, and of the dry land.

A chapter on crustaceans as parasites and messmates is full of quaint things; we read of a little crab, *Hapalocarcinus marsupialis*, in which the female allows herself to be imprisoned within a cage or "gall" of living coral; of *Melia tesselata*, which carries a sea-anemone in each claw and uses it as a living weapon; and of the extraordinary life-histories of some of the parasitic forms. The contact of crustaceans with human life is illustrated by the palatable lobsters and crabs, shrimps and prawns, by the part which minute forms play in the economy of the sea, by the unique case of the species of Cyclops which is the intermediate host of the guinea-worm, and by borers like the gribble. A short account of Crustacea in the past completes the book, apart from useful appendices on collecting and on literature.

In every respect Dr. Calman's book is a success; it is as instructive as it is interesting, as careful as it is picturesque. It is an admirable introduction not merely to Crustacea but to natural history. In connection with a second edition, we venture to suggest that the author should consider the advisability of adding another twenty pages with tables helping the student to identify the commoner British forms. This seems all the more feasible when we notice the numerous excellent illustrations of British forms with which the book is already provided. But in the meantime we offer the author our congratulations.

THE NUTRITIONAL VALUE OF INDIVIDUAL PROTEINS.

NOW that the composition of the various foodstuffs is becoming better known, physiologists can apply themselves with renewed vigour and greater success to the problem of the part which each plays in nutrition. In this relationship most interest attaches to the proteins, and it is with this important class of substances that Dr. Osborne and Dr. Mendel have commenced what promises to be a most valuable series of researches.[1] It has long been known that gelatin is an insufficient food, and this fits in with the absence of certain molecular groupings (tyrosine and tryptophane) from its composition. More recent experiments have shown that other "imperfect" proteins—for instance, the zein of maize—are also imperfect from the nutritional point of view. There are, however, great difficulties in carrying out investigations on the effect of administering the necessary nitrogen in the shape of a single protein. In order to eliminate individual differences in animals, the experiments must be numerous; but perhaps the greatest drawback of all is the fact that a monotonous diet in itself produces distaste for food, so that the experiment is usually brought to an end by the animals refusing to take what is offered them after a comparatively short period of time.

In the present experiments rats were selected as the object of attack; they can be utilised in large numbers, and, being small animals, a comparatively limited supply of the purified protein will last a long time. Whether the results obtained are applicable in all details to other animals, man included, one feels a little chary in deciding, the proverbial association of mice and men being hardly sufficient grounds for supposing that men and rats are exactly similar in metabolic habits. The rat's span of life is much shorter than that of the larger animals, its first year corresponding roughly to the first thirty years of a man's life.

The two American physiologists mentioned have, however, been remarkably successful in avoiding the bad effects of a monotonous diet; but whether this was due to luck or to certain precautions they took is not quite clear from their publication. Whichever explanation is the correct one, they succeeded in keeping their animals alive for many months. They record numerous experiments in which casein formed the sole nitrogenous constituent of the dietary, and the animals exhibited no sign of ill-health or loss of weight. One animal lived for nearly a year on a diet in which the only protein given was the glutenin of wheat.

The authors direct attention to a most important point which is frequently neglected in such experiments. The metabolism of a growing animal is a different story from that of the adult. This is recognised empirically by practical physicians; it is recognised in the discussion which has taken place in the daily Press and elsewhere on the nutritive value of the different kinds of bread. But the reason for such a belief is still in the region of the unknown. We have no certain knowledge of what are the food constituents, no doubt present in quite small quantities, which are of special value in stimulating growth in young animals. Drs. Osborne and Mendel quite clearly see the problem, but so far they have not solved it. Casein, the protein selected for their most numerous experiments, is the principal protein of milk, the most important of the foods taken by the young; and yet they found that this dietary, given to young rats, maintained their weight, but led to little or no growth.

If we believe the exaggerated statements in the advertisements of foods consisting of this protein freed more or less completely from the other constituents of milk, we should be led to think them extremely valuable substitutes for the untreated article. Practical experience has shown that this is not the case, and the careful experiments which have prompted these remarks have the most important practical outcome in showing the danger of tampering with this essential article in the dietary of infants. Any attempt to "purify" it by removing constituents which are quite as important as the protein, and may be, from the health and growth point of view, even more important, is fraught with peril to the public.

ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held on November 30, when the report of the council was read and Sir Archibald Geikie delivered his presidential address. In the evening the anniversary dinner was given in the Hotel Metropole, and the speakers included Lord Justice Buckley, who proposed the toast of the Royal Society, Lord Alverstone (Lord Chief Justice), the Lord Mayor, and Dr. A. W. Ward (president of the British Academy).

In response to an appeal from the council for funds for the construction of additional buildings for ad-

ministrative and other purposes, that are required to meet the rapid extension of the work of the National Physical Laboratory, and for alterations needed to enable the testing work now carried on at Kew to be removed to Bushy, the Treasury has signified "that in addition to the sum of 5000*l.* inserted in the Estimates for the current year, My Lords will be prepared to ask Parliament to vote two further instalments of the same amount in 1912–13 and 1913–14, on the understanding that the whole scheme will be completed with this assistance." Plans for the buildings have accordingly been prepared, and their erection will be proceeded with at an early date.

At the request of the council, the Admiralty placed the services of H.M.S. *Encounter* at the disposal of the observers sent out by the Joint Permanent Eclipse Committee to observe the solar eclipse of April 28, 1911, and Captain Colomb and his officers and men rendered very efficient assistance to the work. The weather conditions were not very favourable, and two minutes of the 217 seconds of totality were lost. Under these adverse conditions one fairly good photograph was secured by the 3-foot coronograph with the Abney 4-inch lens of 33 inches focal length. With the short focus prismatic camera the whole hydrogen series from H_α to H_2 was secured at the beginning of the second "flash," and, although not adding much to previous knowledge, this is the first time H_α has been photographed at an eclipse.

Satisfaction was expressed by the council at the consent of Sir Joseph Larmor to be nominated for the office of senior secretary of the society for another year in view of the detailed preparations for the celebration of the society's 250th anniversary next year. A minute of the council states that "it is desirable that the secretaries be not so re-elected as to hold office for a period exceeding ten successive years," and under this rule Sir Joseph Larmor would in the ordinary course have retired on November 30. The council expressed the opinion, however, that on account of the celebration next year it would be detrimental to lose the advantage of the senior secretary's long experience and intimate knowledge of the work of the society, while at the same time the task of his successor would be made unduly onerous. This opinion was confirmed by the re-election of Sir Joseph Larmor as secretary at the anniversary meeting on November 30.

After referring to the losses by death which the society had suffered during the past year, the president directed attention to some points in the council's report not mentioned above and to the scientific work of the medallists. Subjoined are some extracts from the address :—

Presidential Address.

In my address last year I adverted to the history of seismological observation in this country and to the part taken in the development of this branch of observational science by our associate, Dr. Milne. I expressed the hope that means might be found to place his important service on a more permanent footing, with an enlarged staff and more generous financial aid. Though no important advance has yet been made towards the realisation of this hope, the subject has not been lost sight of, and at least one useful step has been taken in the more complete equipment of Eskdalemuir Observatory as a seismological station. There are now installed there the complete Galitzin apparatus and the twin Milne apparatus, which record photographically, and also the Wiechert and the Omori instruments, the observations of which are recorded on smoked paper. To Prof. Schuster we are indebted for his generosity in presenting the Galitzin apparatus. The various instruments, when completely put into working order, will supply valuable material for a comparison of results, and will provide an important addition to the network of seismological stations in this country. The addition of this seismological work to the other duties of the superintendent of the Eskdalemuir Observatory has shown that an increase of the staff under his supervision is imperatively required. The Gassiot Committee, after a full consideration of the subject, has recommended that a grant in aid for a limited period should be made by the Royal Society, and the council, approving of the proposal, has granted a sum of 450*l.* for the purpose of supplying an additional observer for two years, after which some other more permanent arrangement must be provided. In the meantime, the council has been gratified by the gift of 200*l.* from Mr. Matthew Gray for the purpose of assisting the progress of seismology at Eskdalemuir.

Fellows are aware that for many years past the society has been conducting researches into the cause and prophylactic treatment of tropical diseases, and that these researches are still in progress. Much information has been collected; and it is satisfactory to know that, since steps have been taken to remove the native population from the fly-belts, the areas affected by one of the most terrible of these maladies, sleeping sickness, have been considerably restricted. But much remains to be accomplished before the knowledge of the subject can be made as complete as it should be. As will be seen from the report of the council, the investigation is now about to be extended far beyond the bounds originally contemplated. It has been plausibly suggested that sleeping sickness may be transmitted from other sources than infected human beings, and the question arises whether the wild animals of tropical Africa may possibly supply the trypanosomes of that disease. Accordingly, at the request of the Colonial Office, the Royal Society has organised and despatched a new commission, under the directorship of Sir David Bruce, for the purpose of studying on the spot what may be the relation of the native fauna of Nyasaland and other parts of Africa to the spread of human trypanosomiasis, and what trypanosome diseases may affect the domestic animals of that region. The composition of the staff has been carefully considered with a view to secure adequate attention to each of the various branches of investigation that are embraced in the wide inquiry which is projected. It is interesting to know that Lady Bruce, who has all along been one of the most efficient observers in Africa, again accompanies her husband on this fresh expedition. I may add that she is not the only lady engaged under our auspices in Africa; Miss Robertson, who has had considerable experience in the study of trypanosomes, has volunteered her services in Uganda, and is now at the Mpumu laboratory tracking the development and transmission of the organisms to which trypanosomiasis is due.

The "Catalogue of Scientific Literature for the Nineteenth Century," on which the committee of the Royal Society has now been engaged for more than fifty years, is speedily approaching completion. The material for the final part (1883–1900) of the general catalogue, which is classified under authors' names, has been collected and sorted, and is nearly ready to pass through the press. Of the subject-indexes of scientific papers for the nineteenth century, two volumes, pure mathematics and mechanics, have been published; and the index for physics, in two volumes, is well under way. While the committee does not claim perfection in detail for the classification of the subject-matter of those sciences, and while it is aware that the arrangement of so great a mass of material which must be condensed into small space will always be liable to technical criticism in details, it nevertheless believes that no person who in future shall set about a general investigation or an historical survey in any department of one of these sciences can afford to neglect consultation of this index. It was felt to be worth while by so great a man as Thomas Young, a hundred years ago, to devote a large amount of time to the compilation of a classified index of the literature of natural philosophy up to that date, when the achievement was just within the range of private enterprise. The immense volume of the scientific literature of the last century could have been digested only by some corporate organisation; and the whole scientific world has signified in advance its obligation to the committee of the society and to the generous benefactors who have assisted the society in the work when its own funds had been depleted by undertaking the continuation

of the same work in the twentieth century as the "International Catalogue of Scientific Literature."

Having gone to so much trouble and expense in the preparation of the materials for these subject-indexes, the society is naturally desirous to see that the results become accessible to the scientific public, for whose use the volumes are intended. All the funds which the Royal Society can possibly devote to this work are necessary for its completion; thus there can be no question of free exchange, as was the case with the earlier volumes, however much the Royal Society might desire it. But, as the fellows are already aware, the Cambridge University Press has consented to undertake the entire risk of printing and publication, and has agreed to sell the volumes at a very moderate price. We are informed that the volumes of the index already issued have, for some reason, not yet attracted the attention among universities and public libraries that was confidently anticipated. I have therefore thought it desirable to bring this matter to notice to-day.

On July 15 of next year the Royal Society will have lived for exactly two centuries and a half. Looking back upon this long career, and considering the friendly relations which the society has for generations maintained with the men of science in all quarters of the globe, the president and council have thought that the occasion will be one which ought not to be passed over in silence, but which deserves to be marked in some worthy way. They have accordingly decided to invite the chief universities, academies, scientific societies, and other institutions in this country, in our colonial dominions, and abroad, to send delegates hither to join with us in celebrating our 250th birthday. The invitations will be issued next month, so as to allow ample time for the selection and the arrangements of the delegates and for our own preparations here. Our patron, his Majesty the King, has been pleased to signify his appreciation of the importance of our proposed celebration. Though the details of the function have not yet been settled, it is thought that the first reception and welcoming of our guests should be held in our own rooms, which, with their portraits and other memorials of our past, will doubtless be of interest to the visitors. For the banquet, at which the fellows and their guests will dine together, we hope to enjoy the use of a large hall specially lent to us for the occasion. Considering the early association of the Royal Society with Gresham College and the City, we trust that some opportunity will be afforded to us of renewing that intercourse, and thus of allowing our delegates to partake of the well-known hospitality of London. There will doubtless be a good deal of private hospitality. Of course, every facility will be arranged for our guests to see public buildings, museums, libraries, and other objects of interest. At the end of the function in London, the delegates may not improbably be invited to visit the Universities of Oxford and Cambridge.

As a permanent memento of the occasion, the council has decided to reproduce in facsimile the pages of the charter-book, containing the signatures of the fellows from that of the founder, Charles II., down to the present day. This interesting volume is now in course of preparation at the Oxford University Press. It has also been arranged to issue a new edition of the society's "Record," in great part rewritten, closely revised, and brought up to date. This volume is also in progress.

MEDALLISTS, 1911.

THE COPLEY MEDAL.

The Copley medal is this year awarded to Sir George Howard Darwin, for his long series of researches on tidal theory, including its bearing on the physical constitution of the earth and on problems of evolution in the planetary system.

As regards the actual oceanic tides, he has perfected the method of harmonic analysis initiated by Lord Kelvin, and has greatly promoted its practical application by the invention of simplified methods of ascertaining the tidal constants of a port from the observations and of framing tide-tables. In another series of researches the tides of a solid planet of slightly viscous material are investigated, including the consequent secular changes in the motion of the planet and of the tide-generating satellite. He traced from this point of view the past history of the earth and moon, and was led to the now celebrated hypothesis that the latter body originated by fission from its primary when in a molten state.

He has further studied in great detail the classical problem as to the possible figures of equilibrium of a rotating mass of liquid and their respective stabilities, which has engaged in succession the attention of Maclaurin, Jacobi, Kelvin, and Poincaré. The difficult theory of a binary system composed of two liquid masses revolving in relative equilibrium, now known as Roche's problem, has been greatly developed and extended by him. Such investigations have, of course, an important bearing on the theory of the evolution of the earth-moon system already referred to.

The above is a mere summary of the main lines of Sir George Darwin's activity. There are, in addition, a number of highly important memoirs on more or less cognate subjects. For example, in dealing with the question as to the degree of rigidity of the earth as it now exists, he has treated it from various points of view; he has considered the theory of the long-period tides, and the stresses produced in the interior by the weight of continents and mountain chains. Mention should also be made of remarkable papers on the history of meteoric swarms, and (in the domain of the more classical astronomy) on periodic orbits.

ROYAL MEDALS.

The assent of his Majesty the King has been signified to the following awards of the two Royal medals:—

The Royal medal on the physical side was assigned to Prof. George Chrystal, of Edinburgh University, on account of his contributions to mathematical and physical science, especially, of late years, to the study of seiches on lakes. Conspicuous in his early years as one of Clerk Maxwell's principal lieutenants, it is to him that we owe the experimental proof of the extreme precision of Ohm's law of electric conduction (Brit. Assoc. Report, 1876). His memoir on the differential telephone (Trans. Roy. Soc. Edin., 1880) was a notable early extension of the theory and practice of Maxwell's principles as regards inductances, now become more familiar when power transmission, as well as telephonic intercourse, proceeds by use of alternating currents. His duties as a teacher of mathematics led to the "Treatise on Algebra," which, besides being a book of original vein, was the earliest systematic exposition in our language of the more rigorous methods demanded in recent times in algebraic analysis. But this purely mental discipline, and its continuation in various memoirs on abstract mathematics, could not wholly occupy a mind trained originally in the school of physical science. Of late years Prof. Chrystal had been engaged with great success in a most interesting subject of research, in the theory and the observation of the free persisting oscillations of level in lakes, first observed and analysed by Forel on the Lake of Geneva.

At the moment when the council was adjudicating this medal it was unaware that the illustrious mathematician at Edinburgh was then lying on his death-bed. He had been in failing health for some time, but the latest news was more favourable. The end came, however, before he could learn that a Royal medal had been assigned to him. In these circumstances it was felt that the award should not be cancelled, but that the medal should be transmitted to his family as a visible token of the admiration with which the Royal Society regards his life-work. On appealing for the sanction of the Royal donor of the medal, his Majesty was pleased to approve of our proposal, and to add an expression of his condolence: "The King trusts that you will be so good as to convey to the family the assurance of his Majesty's sincere sympathy in the terrible loss that they have sustained, through which so distinguished a career has been brought to a close." Those who had personal acquaintance with Prof. Chrystal mourn the extinction of a life full of charm and brightness.

The Royal medal on the biological side has been awarded to William Maddock Bayliss, F.R.S. During the last twenty-five years the part taken by Dr. Bayliss in the advancement of physiology has perhaps been unequalled by any other physiologist in this country. His work has ranged over a wide field. In his earlier papers dealing with the electrical phenomena associated with the excita-

tory state in glands and contractile tissues, he brought forward results which were, at the time, entirely novel, and have formed the basis of all subsequent investigations. His paper with Starling on the electrical phenomena of the mammalian heart was the first to give the correct form of the normal variation, as confirmed by later investigations with the string galvanometer.

Another subject which has engaged his attention at intervals during the whole of his career has been the question of the innervation of the blood-vessels. A third group of researches is represented by those on the innervation, intrinsic and extrinsic, of the intestines. A fourth group of papers deals with the mechanism of the pancreatic secretion. These researches, which by themselves would be sufficient to justify the award of the Royal medal, were also carried out in partnership with his colleague, Prof. Starling. The discovery of secretin afforded for the first time a convenient and easy method of obtaining pancreatic juice in large quantities. The investigation of the properties of pancreatic juice and of the activation of its chief proteolytic ferment by another ferment, enterokinase, secreted by the intestinal mucous membrane, has led Bayliss to a further series of researches on the mode of action of enzymes and on the closely related questions with regard to the nature of colloidal solutions. The value of this work has been universally recognised.

Davy Medal.

The Davy medal is this year assigned to Prof. Henry Edward Armstrong, F.R.S., on account of his researches in organic and in general chemistry.

For many years he has been engaged, partly alone and partly in collaboration with many of his students and others, in the investigation of a number of important problems in organic chemistry. His series of memoirs on the terpenes, on the chemical and physical relationships which obtain among the isomerides of the naphthalene and the benzene series, and on physiological chemistry, have established a strong claim for recognition.

In addition to his direct scientific work, he has taken an active part in the discussion and criticism of current theories, and has put forward views on chemical change and on other subjects which have suggested fruitful lines of inquiry. Gifted with a scientific imagination, interested in the work of others, exceptionally well informed as to recent progress, not only in chemistry, but also in cognate sciences, he has had a stimulating effect on his fellow chemists, and has done much to bring together for their mutual benefit the workers in different fields.

Hughes Medal.

The Hughes medal has been assigned to Charles Thomson Rees Wilson, F.R.S., in recognition of the value of his contributions to our knowledge of the nuclei produced in dust-free gases, and of his investigations upon the nature and properties of ions in gases. Following up the well-known work of Aitken on dust nuclei, Mr. Wilson devised a special apparatus for producing a sudden cooling of a gas saturated with water vapour. After completely freeing the gas from dust particles he found that water was condensed on a few nuclei after an expansion of volume greater than 1·25, and that a dense cloud was formed when it exceeded 1·38. This work was in progress at the time of the discovery of X-rays. He immediately tried the effect of passing this radiation through the gas in the expansion chamber, and found that a dense cloud of fine water drops was produced for all expansions greater than 1·25. In this way he showed that the charged ions produced in gases by the X-rays became nuclei for the condensation of water at a definite supersaturation.

This condensation property of ions, discovered by Wilson, was utilised by Sir J. J. Thomson to count the number of ions present, and to determine that fundamental electrical unit, the charge carried by an ion in gases. Recently Mr. Wilson has perfected the expansion method to detect the effects of individual α and β particles.

A further study by this extraordinarily delicate method promises not only to afford a practical means of counting the α and β particles in a gas, but also to throw light upon some of the more important and recondite effects produced by the passage of different types of ionising radiation.

NOTES.

The Birstall Urban District Council initiated about twelve months ago a movement to commemorate, in his native town of Birstall, the distinguished philosopher and man of science Dr. Joseph Priestley, the discoverer of oxygen. The town of Birstall, which is the birthplace of other distinguished men and women, including Margetson, Primate of Ireland, Curwen, of tonic sol-fa fame, and others, was a fitting birthplace for a man of clear vision, cool thought, and high speculation such as Priestley. Backed by the high Adwalton Moor on the north and north-east, the Priestley homestead of Fieldhead looked out on a fine panorama, with Castle Hill, Huddersfield, and smaller Yorkshire towns rising high on either side of Batley and the stretch beyond. For many years the inhabitants of Birstall have been desirous that something should be done to express by permanent memorial the town's pride in her illustrious son, and the present movement is the outcome. It is proposed to erect a life-size figure of Dr. Priestley on a handsome pedestal, to be placed in the most prominent position in the large market-place. For this purpose 1000*l.* is required, and already about 450*l.* has been secured; but the local committee is now desirous of appealing to a wider public, and especially to all interested in the various branches of chemistry. The London City and Midland Bank, Batley, are the bankers of the "Priestley" Fund.

On Tuesday, December 5, a deputation of aëroplane and aëromotor manufacturers, with representatives from the Royal Aëro Club and the Aëronautical Society, waited on Colonel Seely in connection with the proposed Military Aëroplane Competition. The deputation, which was introduced by Sir Chas. D. Rose, asked for immediate conditional orders so that manufacturers might have some guarantee of return for the outlay necessary for entering the competition, pointing out that they, representing a struggling and unsupported industry, were asked to compete against flourishing and State-aided industries from abroad in an international competition. Colonel Seely in his reply stated that, with the exception of the principal prize, not all the prizes would be open to the world, and intimated that some orders would be given before the competition. He further said that the answer to the question whether orders would be given for all machines passing the tests would be found in the specification for machines and the rules of the competition, which would be published in about a fortnight's time, and that it was the intention that aëroplanes selected for Government service, which would not be confined to one type, should be manufactured in this country by the civil industry and not in Government factories. He intimated that large orders would be given for the chosen machines, and that if the consensus of the manufacturers' opinion was against holding the competition early in the summer (June) he would see that recommendations to that effect were made in the proper quarter. The deputation subsequently decided to forward a resolution that it would be in the best interests of the competition to postpone it until September.

An interesting demonstration in connection with electro-chemical culture will be given on Saturday, December 9, at 4 o'clock, at the Royal Botanic Society's Gardens in Regent's Park, when practical demonstrations will be made with an electric apparatus to show the effect of electricity on the germination of seeds.

The Physical Society's annual exhibition, which is to be held on Tuesday, December 19, at the Imperial College of Science, South Kensington, will be open in both the

afternoon (from 3 to 6 p.m.) and in the evening (from 7 to 10 p.m.). The Hon. R. J. Strutt, F.R.S., will give a discourse at 4.30, and again at 8 p.m., on "Electric Discharge and the Luminosity which survives it." About thirty firms will exhibit apparatus.

WE regret to see announced the death, on November 23, of Mr. Arthur Cottam, at seventy-five years of age. Employed as an official in a Government department during a great part of his life, he was an enthusiastic amateur astronomer. He was elected a fellow of the Royal Astronomical Society so far back as 1862, and was one of the original members of the British Astronomical Association, being its secretary from its foundation in 1890 to 1892, when he resigned owing to increasing pressure of official duties. In 1898 he became director of the Jupiter section of the association, an office which he retained until 1903. Mr. Cottam is best known by an excellent star atlas, "Charts of the Constellations," which he published in 1889. These charts show all stars down to about the 6·5 magnitude, from the North Pole to between 35° and 40° of south declination, for the epoch 1890. Originally projected as companions to Webb's "Celestial Objects" and Smyth's "Bedford Catalogue," their scope was considerably enlarged, and they show many original features. Each map usually gives one constellation only with the region around it, and the brighter stars have much larger discs than usually given, so that the leading stars in the maps are those which catch the eye by their brightness in the heavens.

IN *Die-Woche* of November 25 we find an article on the Middle European earthquake of November 16. It describes the districts which were most disturbed, the one most strongly shaken being that of the northern Alps. The central earthquake station in Strassburg places the origin to the south-east of Lake Constance. From time observations the epicentral area lies in 47 degrees north latitude and 10·30 east longitude. But before anything definite can be said as to this and other matters connected with earthquake, it is necessary to wait for reports from other stations. In the article reference is made to the geological character of the northern Alps and the Rhine Valley, the numerous faults which occur, and the relationship of these to tectonic earthquakes.

PROF. W. C. BRÖGGER (Christiania), Geh. Rath Prof. T. Curtius (Berlin), Prof. P. A. Guye (Geneva), and Geh. Regiersrung Rath Prof. H. Rubens (Berlin), have been elected honorary members of the Royal Institution. Dr. W. Bateson, F.R.S., has been appointed Fullerian professor of physiology for a term of three years. At a meeting of the managers of the institution on December 4 the following resolution was passed unanimously:—"That the managers offer their special thanks to the Fullerian professor of chemistry for his munificent gift to the institution in the decoration and furnishing of the lecture room, and at the same time they wish to express their high appreciation of the occasion upon which it has been made, namely, in commemoration of his having, on October 22, 1911, occupied the chair of chemistry as long as it was held by Faraday."

THE following are among the lecture arrangements at the Royal Institution before Easter:—Dr. P. Chalmers Mitchell, a Christmas course of six illustrated lectures on the childhood of animals, adapted to a juvenile auditory: (1) "Introductory"; (2) "The Duration of Youth"; (3) "Colours and Patterns of Young Animals"; (4) "Young Animals at Home"; (5) "The Feeding of Young Animals"; (6) "The Play of Young Animals." Dr. W. Bateson, six lectures on the study of genetics; Prof. E. G. Coker, two lectures on optical determination of stress and some applications to engineering problems; Dr. T. Rice Holmes, three lectures on ancient Britain; Prof. A. W. Bickerton, two lectures on the new astronomy; Prof. A. M. Worthington, two experimentally illustrated lectures on the phenomena of splashes; Mr. F. A. Dixey, two lectures on dimorphism in butterflies: (1) "Seasonal Dimorphism," (2) "Sexual Dimorphism"; the Rev. John Roscoe, two lectures on the Banyoro: a pastoral people of Uganda: (1) "The Milk Customs," (2) "Birth and Death Customs"; Sir J. J. Thomson, six lectures on molecular physics. The Friday evening meetings will commence on January 19, when Sir James Dewar will deliver a discourse on heat problems. Succeeding discourses will probably be given by Prof. Bertram Hopkinson, Dr. J. Mackenzie Davidson, Dr. J. A. Harker, the Rt. Hon. Sir John H. A. MacDonald, Mr. G. K. B. Elphinstone, Dr. W. J. S. Lockyer, Mr. F. Soddy, Prof. D'Arcy W. Thompson, Sir J. J. Thomson, and other gentlemen.

THE Lord Mayor will preside at the sixth annual meeting of the National League for Physical Education and Improvement, to be held at the Mansion House to-morrow, December 8, at 3.30 p.m. The meeting will be addressed by Sir Archibald Geikie, president of the Royal Society; the Lady St. Davids; Dr. Christopher Addison, M.P. (on legislation and public health); Prof. Bostock Hill, county medical officer of health for Warwickshire (on the organisation of a National Health Week); Mr. Henry Jephson, and others. Among those who have promised to attend are Sir Lauder Brunton, Sir John Tweedy, Sir Wiliam Church, Sir Edward Brabrook, Muriel Viscountess Helmsley, Lieut.-General Sir Robert Baden-Powell, Admiral the Hon. Sir E. Fremantle, and Archdeacon Sinclair.

A SPECIAL weights and measures committee of the Central Chamber of Agriculture recommended recently that agricultural produce should be sold by weight. It reported that suitable weights were the lb., the cental (100 lb.), and the short ton of 2000 lb. Dealing with this suggestion in a circular, which has been distributed, the Decimal Association points out that advocates of the metric system offer a solution of the difficulty by proposing that farmers should urge the compulsory introduction of the metric system into this country. Less disturbance would result from the adoption of the metric system than would follow the introduction of the cental and short ton, for the reason that the larger measures of the metric system differ but little from the cwt. and ton. The increase of the lb. by about 10 per cent. to make it equal to the half-kilo would lead to a metric cental of 110 lb. (100 metric pounds), and a ton of 2000 metric pounds equal to 2204 present lbs. Our Consul at Copenhagen reports that the Metric System Act, which will come into force next April, was passed by the Danish Upper and Lower Houses, in both of which the majority are agriculturists.

BY the authority of the Dominion Government, the director of the Canadian Meteorological Service has established a department of physics in connection with the Central Office at Toronto. Mr. John Patterson has been placed in charge of this new department; and it is proposed to carry on research work in atmospheric electricity, solar radiation, ionisation, and the exploration of the upper atmosphere. A kite station has been equipped near the magnetic observatory some fourteen miles from Toronto, and good results are being obtained. Since February last registering balloons carrying the Dines meteorograph have

been sent off with regularity on the international days, and of sixteen balloons liberated, eight have been returned to the Central Office with good records. In comparison with the results obtained in Europe, the percentage of successful ascents may be regarded as very encouraging. The heights reached have varied from 11·2 to 23·2 kilometres. The isothermal layer has been found at an average height of 13 kilometres. The lowest temperature recorded was −70° C. at 15 kilometres on July 5, and the highest altitude reached was 23·2 kilometres on September 9, when the lowest temperature, −55·5° C., was recorded at 14 kilometres.

THE premises of the Institute of Chemistry, the lease of which will expire shortly, and cannot be renewed, have become inadequate for the increasing activities of the institute. To carry on the work, the council of the institute requires new buildings, which should include more commodious meeting rooms, library, laboratories, examination rooms, and offices. It is proposed to begin the preparation of plans next year, and it is estimated that the necessary building and fittings will cost about 15,000*l*. An appeal has been made to fellows and associates of the institute, which has already resulted in the receipt of contributions and promises amounting to more than 8000*l*. With more than half of the required sum assured, it may be confidently hoped that the appeal will result in the completion of the necessary amount at an early date. It is gratifying to notice that the preliminary list of contributions includes the names of some of the great city companies and of business firms not directly connected with the institute. Contributions may be forwarded to the president, Dr. G. T. Beilby, F.R.S., at 30 Bloomsbury Square, London, W.C., or may be sent direct to the account of the Institute of Chemistry (Buildings Fund) with the London County and Westminster Bank, 214 High Holborn, London, W.C.

THE annual meeting of the American Association for the Advancement of Science will be held this year in Washington on December 27–30. The retiring president, Dr. A. A. Michelson, will, on the evening of December 27, introduce the new president, Dr. C. E. Bessey, of the University of Nebraska, and afterwards deliver his address on "Recent Progress in Spectroscopic Methods." On December 27 the presidential addresses in the sections will be:—the resins and their chemical relations to the terpenes, Mr. Frankforter; adaptation, Mr. Reighard; some current conceptions of the germ plasm, Mr. Harper. On December 28:—work of the electrical division of the Bureau of Standards, Mr. Rosa; aërial engineering, Mr. Rotch; the teaching of general courses in science, Mr. Hill. On December 29:—on the foundations of the theory of linear integral equations, Mr. Moore; the independence of the culture of the American Indian, Mr. Dixon; the cause of high prices, Mr. Burton. The presidents of the sections for the ensuing year are as follows:—A, Mathematics and Astronomy, E. B. Frost, Yerkes Observatory; B, Physics, R. A. Millikan, University of Chicago; C, Chemistry, F. K. Cameron, U.S. Department of Agriculture, Washington, D.C.; D, Mechanical Science and Engineering, C. S. Howe, Case School of Applied Science, Cleveland, Ohio; E, Geology and Geography, B. Shimek, State University of Iowa; F, Zoology, H. F. Nachtrieb, University of Minnesota; G, Botany, F. C. Newcombe, University of Michigan; H, Anthropology and Psychology, G. T. Ladd, Yale University; I, Social and Economic Science, J. Pease Norton, Yale University; K, Physiology and Experimental Medicine, W. T. Porter, Harvard Medical School, Boston; L, Education, E. L. Thorndike, Columbia University. Thirty scientific and other learned societies have indicated their intention to meet at Washington on the same dates in affiliation with the American Association for the Advancement of Science. The permanent secretary of the association is Dr. L. O. Howard, Smithsonian Institution, Washington, D.C.

THE twentieth report of the Board of Health on Leprosy in New South Wales for the year 1910 (dated July 31, 1911) states that nineteen lepers remained under detention at the lazaret, and that five new cases were reported in 1910. The histories of these new cases are detailed together with surveys of the white patients remaining under treatment. Nine excellent plates of the condition of some of the lepers are appended.

IN *The Quarterly Journal of Experimental Physiology* for October (iv., No. 3) Messrs. Vernon and Stolz discuss the influence of forced breathing and of oxygen on athletic performance. It is well known that several deep inspirations enable the breath to be held for a longer period than without this preliminary, but it is shown that to obtain this result the forced breathing should be continued for two or three minutes. An addition of oxygen much lengthens the period during which the breath can be held. Thus Mr. Vernon found that after six minutes of forced breathing of air, followed by four breaths of oxygen, he could hold his breath for no less than 8m. 13s.

IN *Himmel und Erde* for November (Jahrg. 24, Heft 2) Dr. E. W. Schmidt, under the title of "Die Panspermie-Hypothese," gives an account of the views of Arrhenius on the possible transference of living germs through interstellar space from one star or planet to another; Prof. Ficker continues his series of articles on bacteria as enemies and friends of man; and Dr. Emil Carthaus discusses the origin of pearls, and gives many interesting historical details concerning them.

IN a recently published pamphlet entitled "The Fight against Tuberculosis and the Death-rate from Phthisis" (Dulau and Co., pp. 35, price 1s. net), Prof. Karl Pearson criticises the evidence which has been advanced in favour of a belief that the prevalence of phthisis can be, or has been, diminished by measures intended to reduce the opportunities of infection. Prof. Pearson strongly urges the importance of some constitutional factor, and publishes diagrams which, in his opinion, render it difficult to suppose that the fall in the phthisis death-rate which has been observed in modern times can be attributed to increased segregation of the diseased, bettered environment, or changes in treatment. The pamphlet will repay perusal, although its style, which is more vigorous than urbane, is not likely to facilitate an impartial consideration of Prof. Pearson's views.

THE report of the Manchester Museum for 1910–11 contains plans and a view of the front elevation of the proposed new wing, part of which is now in course of construction, while the remainder is reserved for the future. It appears that in the original scheme for the natural history museum Egyptology and anthropology were not included; but during the last thirty years large collections in these subjects have accumulated, which require adequate accommodation, and it is for these that the new building is being erected. The cost of the whole scheme of extension is estimated at 10,000*l*., of which 5000*l*. has been given by Mr. Jesse Haworth, while 2825*l*. has been raised by public subscription. The general progress of the museum has been very satisfactory during the year, and the attendance at the courses of lectures fairly good.

IN the second part of the Transactions of the Bristol and Gloucestershire Archæological Society Miss M. L. Bazeley contributes an important paper on the relations of the Forest of Dean with the Crown during the twelfth and thirteenth centuries. She describes in detail the ancient boundaries of the forest, the animals found in it, and the periodical Royal visits for the purpose of sport. Fallow deer were abundant, with red deer and roes in smaller numbers. Wild boars seem to have been exceedingly numerous. On one occasion King John had twenty captured for use on the Feast of St. David at Westminster; twenty boars and sixty sows were sent to him for the Feast of the Nativity, and Henry III. had as many as a hundred for the Christmas dinner in 1254. These requisitions seem to have seriously reduced the supply. We hear of hunts of wolves and wild cats in 1281, when of the former we are told that they "as injurers of the venison frequently return for the venison and stay in the said wood, on account of the thickness thereof."

THE report of the Marine Biological Association of the West of Scotland for 1910 indicates that the work of that body has been carried on steadily during the period under review; and it may be noted that a special effort has been made to provide, in full efficiency, all the facilities for study and research available at Millport. A large number of visitors entered the museum and aquarium, the latter of which is steadily increasing in popularity.

IN the November issue of *The Zoologist* Dr. James Murie discusses the introduction of the American slipper-limpet (*Crepidula fornicata*) into this country, and its influence on oyster-culture in Kent and Essex. The mollusc appears to have been introduced into the estuary of the Crouch and other rivers on imported American oysters somewhere about 1880, and by 1893 had become comparatively abundant; it is now too firmly established to be eradicated. Its introduction has entailed considerable extra labour on oyster-beds, as the oysters have from time to time to be dredged and freed from the parasite, which adheres tightly to their shells. But this is not all, as this constant and excessive dredging causes the growing oysters to have broken or imperfectly formed margins to their valves, whereby their commercial value is lowered. Investigations with the view of mitigating the evil appear to be urgently required.

IN connection with the letter from Messrs. Puran Singh and S. Maulik in NATURE of November 23 on the nature of the light from fireflies, it may be mentioned that the subject has been recently discussed in vol. iii., No. 1, of the Annals of the Transvaal Museum by Mrs. A. B. Howard, who observes that this light is unique in being unaccompanied by perceptible heat, and is therefore produced at the least possible expenditure of energy. In the American species, on which the investigations were made, light is emitted by both sexes, although that of the flightless female is feebler than that of her partner. In the latter the light is produced by a pair of plates lying beneath the thin skin and filling the lower half of the fourth and fifth abdominal segments. These light-giving organs consist of an upper and a lower layer, of which the latter is composed of polygonal cells filled with coarse granules. Although the minute size of the structures renders investigation very difficult, it is considered probable that the light is due to the oxidation of some substance—very likely fatty—contained in the cells of the lower layer of the light-organs.

As those who have studied the subject are aware, there are features connected with "fairy rings" which are not immediately explicable. In the latest paper, which appears in *The Journal of Economic Biology* (vol. vi., No. 4), Miss J. S. Bayliss points out that it is not known how the fungus first infects the soil or why it grows in rings; but otherwise the paper provides acceptable explanations of observed features and experiments in connection with the ring growth of *Marasmius oreades*. Two zones are easily recognised, an inner dark green grass zone and a dead grass zone where the fungus is growing. Dr. Bayliss directs attention to another dark green zone on the outside that is particularly well developed in September. The action of the fungus is complicated, since it apparently produces a stimulating effect, as shown by the outer green zone, while it excretes a toxic substance leading to the complete destruction of the grass; subsequently it poisons the ground for its own development, and then decomposes into manure for the grass.

DURING the past few years various expeditions from the University of Chicago have secured from the fossil fields of northern Texas the largest and best collection of Permian vertebrate fossils in the world. During last summer an expedition from the University, under the direction of Prof. S. W. Williston, explored the Permian deposits of north-western New Mexico with valuable results. *Science* says that these Permian deposits, of small extent, in Rio Arriba County, were discovered more than thirty years ago, but have been neglected by explorers ever since, and their precise location even was unknown to geologists. As a result of Prof. Williston's excavations, numerous fossils have been shipped to the University, many of which are unknown to science. This collection includes six or seven new genera of reptiles and amphibians, one of which is represented by one of the most perfect skeletons, about 6 feet in length, ever found in any deposit in America.

To *Symons's Meteorological Magazine* for November Mr. F. W. Henkel contributes an interesting article entitled "Is the Zodiacal Light a Meteorological Phenomenon?" The author points out that a complete and satisfactory answer to the question cannot be given, and that our knowledge of the subject is but little greater than was possessed by the first discoverers. Even in recent times considerable confusion has existed between the phenomenon and the aurora. He refers to the various observations made since the time of Cassini, of Paris (about 1683), and to the descriptions of the counter-glow (at an angular distance of 180° from the sun) by Brorsen and others. One of the most recent theories of the latter phenomenon is that suggested by Mr. Innes in NATURE of June 16, 1910.

THE Weekly Weather Report issued by the Meteorological Office gives a summary of the temperature, rainfall, and bright sunshine for the several districts of the United Kingdom for the thirteen weeks ended December 2, which embraces the whole period of autumn. The mean temperature was generally below the average in Scotland, it was in good agreement with the average in Ireland, whilst in England an excess of temperature occurred for the most part. The range of temperature was unusually large, due chiefly to the exceptional heat in the recent abnormal summer, which was prolonged into the early autumn. In the Midland counties the range was 69°, from 94° to 25°, and in the south-west of England it was 71°, from 91° to 20°. The autumn rains have varied considerably in different parts of the kingdom; they were in excess of the average over the eastern portion of Great Britain, in the north-west of England, the south of Ireland, and in the English Channel. The least aggregate autumn

rainfall is 6·88 inches, in the Midland counties, which is 0·48 inch below the normal; whilst in the south-east of England the aggregate fall is 10·47 inches, which is 1·08 inches more than the average. The absolutely largest rain measurement is 13·78 inches, in the north of Scotland, which, however, is 1·82 inches less than the normal. The number of rainy days are nowhere very different from the average, the greatest number being fifty-eight days, in the north of Scotland and in the south of Ireland; the least forty-seven days, in the south-east of England. The duration of bright sunshine was in excess of the average over the entire kingdom, except in the English Channel. The greatest duration is 382 hours, in the south-east of England, which is sixty-nine hours more than usual.

MR. M. A. HUNTER, of the electrical engineering department of the Rensselaer Polytechnic, Troy, has succeeded in producing metallic titanium in a state of purity greater than has been hitherto possible. He uses the method of Nilson and Petersson, *i.e.* reduces the tetrachloride of titanium by heating it with metallic sodium in an air-tight steel bomb capable of withstanding an internal pressure of more than 5000 atmospheres. With a charge of 500 grams of the tetrachloride and 245 grams of sodium, after heating the bomb to redness to start the reaction and then allowing it to cool, he obtained 71 grams of molten metal, 31·5 of coarse and 4·5 of fine powder, as against a theoretical yield of 126 grams. Analysis of the product appears to indicate that the molten material is pure titanium. Messrs. Hunter and Jones find that the density of the metal is 4·50, and its specific heat between 0° C. and 100° C. is 0·1462.

VOL. iv. of the Journal of the Municipal School of Technology, Manchester, a record of the investigations carried out by the staff and students, and published in the technical Press or the Proceedings of scientific societies during the year 1910, is not so bulky as its immediate predecessors, although it runs to 250 pages. The papers reprinted are, on the whole, short, and they deal principally with the applications of electricity in engineering or of chemistry in textile processes. Of the longer papers, those of Prof. Schwartz and his staff on the physical and electrical properties of indiarubber and on the field of the polyphase motor may be mentioned. In an important paper by Prof. Haldane Gee and Mr. Harrison, reprinted from the Transactions of the Faraday Society, the authors bring forward weighty experimental evidence in favour of the electrical theory of dyeing. According to this theory, a basic dye is positively, and an acid dye negatively, charged, and the processes through which the fabric passes before it is brought into the dye are such as to charge it negatively or positively respectively, so that there may be electrical attraction between dye and fabric. The number of "laws of dyeing" which the electrical theory places on a firm scientific basis is remarkable.

AMONG primary plant materials, the pentosans, so widely diffused, form a class of substances the origin and function of which are still uncertain in spite of numerous researches which have been made to throw light on these problems. An interesting contribution to the question is found in a paper by Ciro Ravenna in the *Gazzetta Chimica Italiana* (vol. xli., p. 115). It is shown as the result of a large number of experiments, in which the pentosans were estimated in the very young, primary leaves of the beech and of *Vicia faba minor*, at dawn and sunset, that no marked variation in their amount can be traced during the period of chlorophyllian activity; but at night considerable but irregular variations occur, generally in the direction of increase, but sometimes in that of decrease. Wh[...] however, the stalk of the growing leaf is immersed in [...] nutritive solution containing 2 per cent. of dextrose, a[...] the plant allowed to continue its growth for several da[...] exposed to sunlight in an atmosphere free from carb[...] dioxide, the proportion of pentosans is very largely [...]creased, being often nearly doubled. A similar, but not [...] well marked, result was obtained in experiments in wh[...] the plant continued its growth in the nutritive solution [...] darkness, but in an atmosphere containing the ordina[...] proportion of carbon dioxide. It is contended that [...] pentosans are elaborated, not from the complex p[...] saccharides, such as starch and cellulose, by down-gr[...] changes, as is generally supposed, but that they are form[...] direct from the simple carbohydrates. It is also sho[...] that when the chlorophyllian activity is inhibited, [...] pentosans diminish in relative amount, so that it w[...] appear that, in addition to their other functions, they [...] capable also of acting as reserve material for the plant.

A PROPOSAL for the reform of income tax and est[...] duty is put forward by Mr. Douglas White in T[...] *Economic Journal*, xxi. 83. According to the auth[...] proposed system, the rate per pound at which an inc[...] would be taxed would be proportional to the logarithm [...] the income, so that as incomes increased in geometric pr[...]gression the rate of the tax would increase in arithmet[...] progression. If, as Mr. White proposes, this system w[...] carried out rigorously with the use of logarithm tables, [...] would certainly, as alleged, remove the discontinuities [...] the present system, where what a man pays is regula[...] largely by whether his income falls on a lucky num[...] such as 499*l.*, or an unlucky one such as 501*l.* In practi[...] it would be sure to be simplified by retaining these d[...]continuities, for which a much simpler, obvious rem[...] is possible.

A PAPER on the design of tall chimneys was read [...] Mr. Henry Adams before the Society of Engineers [...] December 4. Tall chimneys ought to be designed up[...] scientific principles so that there is an absolute guaran[...] for their stability. The object of Mr. Adams's paper w[...] to elucidate these principles and apply them to practi[...] There are several rules for determining the height of [...] tall chimney; in some towns 45 feet may be sufficient, b[...] in others 90 feet is the minimum allowed. The height m[...] be determined from the amount of coal burnt, or from [...] length of boiler and flues. Four different rules were gi[...] for the sectional area, depending upon the amount of [...] burnt per hour, the fire-grate area, the horse-power of [...] engine, or a combination of these with the height of [...] chimney. The shape may be square, octagonal, or circu[...] the effective wind pressure varying in each case. T[...] author's formula for wind pressure takes account of h[...] and width, increasing with the distance from the gr[...] and increasing also with reduced width. Eight authori[...] were quoted for the coefficient of pressure for a circ[...] shaft varying from 0·5 to 0·7854. The thickness of [...] brickwork varies 4½ inches every 20 feet in height, [...] the top length will be from one to one and a half bri[...] thick, according to the height and diameter. The over-width at base must be at least one-tenth, and if circular [...] least one-twelfth, of the total height. After the sectio[...] drawn out to suit the conditions, the stability should [...] calculated at each set-off. The principles of stability m[...] be illustrated by considering a solid square brick pier.

MR. LIVINGSTONE SULMAN, president of the Institut[...] of Mining and Metallurgy, delivered an address at t[...] annual prize distribution of the Sir John Cass Techni[...]

Institute on November 29. In the course of his address Mr. Sulman pointed out that the dominant thought which impressed one to-day was the many-sidedness, the increasing scope, and the intense vigour which now marks metallurgical progress. The interaction of associated sciences is now beginning to play its part in the development of metallurgical industries. Certain of the factors of so-called molecular energy find expression in some of the newer processes and phenomena of metallurgy, as shown in the methods adopted to the harnessing of molecular attractions which reside upon the surfaces of solids, to the purposes of ore concentration. These methods, which have, for example, completely changed the economic outlook of the great Broken Hill deposits of silver-lead-zinc ores, are there used to separate the blends constituent in saleable form from the "tailings" left behind after the bulk of the lead and silver have been recovered. But they are applicable, in general, to all sulphide ores, as well as to finely divided metals and non-metals, such as gold, graphite, carbon, diamond, sulphur, and so on; and they are frequently spoken of as "oil processes," from the fact that in several of them oil is used in larger or smaller quantities, usually in smaller. In such processes there are no chemical reactions to speak of; physical forces of previously unsuspected range and power, so far as commercial applications are concerned, have been induced to do the work more easily and much more economically, the force mainly concerned being what is called "surface energy." Equally new, and probably of great importance to the metallurgist of the future, are the developments in colloidal chemistry. The plasticity of clays and "ultra-sliminess" of "slimes" are due to this class of bodies, in which inorganic materials ape the reactions of organic; a clay colloid may almost be said to masquerade as a fatty acid. Mr. Sulman also referred to the extended application of improved magnetic and electrostatic methods for the separation of dry ores, and to catalytic processes of metallurgical importance.

A SELECTED "List of Educational Books for Schools, Colleges, and Self-tuition," issued by Messrs. W. and G. Foyle, 135 Charing Cross Road, London, W.C., has reached us. Nearly all the books included in the catalogue can be supplied secondhand at half the published prices; and Messrs. Foyle will send any book in stock on approval.

MESSRS. WILLIAM WESLEY AND SON, 28 Essex Street, London, W.C., have sent us a copy of the latest issue of their "Natural History and Scientific Book Circular." It contains a catalogue of 356 selected books on natural history, with coloured illustrations, followed by a list of works published by, or on sale with, Messrs. Wesley and Son, who are, it may be added, agents for the Smithsonian Institution and the U.S. Government departments.

MESSRS. J. WHELDON AND CO. (38 Great Queen Street, Kingsway, W.C.) have just issued a supplement to their scientific and geological catalogues. The supplement comprises recent purchases in astronomy, chemistry, geology, palæontology, mineralogy, mining, &c., and includes a small collection of works on applied chemistry, metallurgy, and other subjects.

Erratum.—We are asked to state that in the abstract of Mr. Hutchinson's paper read before the Mineralogical Society (p. 165) the temperature at which gypsum becomes optically uniaxial should be 95° C., not 25° C. The incorrect value was given in the typewritten report received by us, and the error was not corrected in the proof submitted and returned to the printers.

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A NEW COMET, 1911*h*.—A telegram from Kiel announces the discovery of a new comet by M. Schaumasse, at Nice, on November 30. Its position at 17h. 15·9m. (Nice M.T.) was

R.A. = 13h. 12·2m., dec. = 5° 51′ N.,

and its daily motion was found to be +3m. 32s. in R.A. and −13′ in declination; the magnitude is 12·0.

A second telegram gives an observation by Dr. Abetti at Arcetri on December 2, the position at 17h. 26·9m. (Arcetri M.T.) being

R.A. = 13h. 19m. 17·6s., dec. = 5° 24′ 29″ N.

The comet is thus seen to be moving in a south-east direction through Virgo.

BORRELLY'S COMET, 1911*e*.—Borelly's comet, rediscovered by Mr. Knox Shaw on September 19, is approaching both the sun and the earth. As the perihelion passage will take place on December 18, when the comet is nearly in opposition with the sun, and as the comet is moving northwards rapidly, it may become visible with opera-glasses during the latter part of December and in January, 1912 (*L'Astronomie*, November).

THE PRODUCTION OF STAR STREAMS.—A paper by Prof. Benjamin Boss, in No. 629 of *The Astronomical Journal*, discusses, in relation to a star stream he has found among seventy-one large proper-motion stars given in the Preliminary General Catalogue, the somewhat startling suggestion that community of direction and velocity in such streams may be caused by the initiation and maintenance of their motions in an electromagnetic field of universal extent.

The directions and proper motions of eleven of these large proper-motion stars, together with their radial velocities and parallaxes where available, agree so well as to preclude the idea of chance occurrence, and some physical explanation is sought.

Assuming that the stars form from nebulæ, the motion of the latter might explain the phenomena; but the extended nebulæ do not exhibit such *motus peculiaris*, and Prof. Boss seeks the common cause elsewhere.

The suggestion is that the nebulæ are the seat of tremendous ionisation forces producing segregation, and electromagnetic polarities in the segregated masses. In the course of time a relatively strongly polarised mass becomes expelled from the matrix and commences a stellar existence. Initially the directions would be haphazard, but the action of the supposed universally existent electromagnetic field would be to swing the polarised masses into paths along the approximately parallel lines of force. Assuming the B-type stars to be the newest, Prof. Boss finds support in the fact that such stars display random motions, while those in his group of large proper-motion stars, exhibiting community of direction, are of the types F, G, and K. Further, the action of a constant acceleration such as is suggested would tend to level up the differences found in the initial velocities, thus producing the community of velocity observed.

DOUBLE-STAR MEASURES.—In No. 4534 of the *Astronomische Nachrichten* Prof. Burnham publishes a long list of recent measures of double stars related largely to the proper motion of stellar systems contained in his General Catalogue. The measures were made with the 40-inch refractor at the Yerkes Observatory, and follow on Prof. Burnham's similar publications in the same journal.

In No. 4537 Herr J. Voûte publishes a second list of double-star measures, which will later be published *in extenso* in the Annals of Leyden Observatory.

RADIAL VELOCITY OF α CYGNI.—Some time ago we directed attention to a result obtained by Prof. Belopolsky and Mr. Neuimin in which they found what appeared to be a real difference between the radial velocity of α Cygni as determined from the metallic lines and that determined from the hydrogen and helium lines. At the suggestion of Prof. Frost, Mr. O. J. Lee has examined some measures of the spectrum made by him in 1910, and he fails to find any confirmation of the Pulkowa results. He suggests that the discrepancy found by Neuimin and Belopolsky

may be due to slight differences of complexity in the hydrogen-line images (*Astrophysical Journal*, vol. xxxiv., No. 4).

THE SPECTRUM OF THE OUTER PLANETS.—In No. 4537 of the *Astronomische Nachrichten* Dr. Otto Büry publishes a note in which he shows that the well-known characteristic absorption-band spectrum of the outer planets can be fairly well matched by combining Chappuis's and Schöne's ozone spectra with the spectrum of the higher oxides of nitrogen obtained by Chappuis. As shown on the plate accompanying the paper, the chief bands in Vogel's spectrum of Uranus, for example, are fairly well represented in the ozone and peroxide spectra; such differences as exist might perhaps become explained if the terrestrial spectra were experimented with more exhaustively under different temperatures and pressures; for Chappuis has shown that the ozone spectrum is sensitive to such changes.

SUN-SPOTS AND CLIMATE.—Considering the climate of Berlin as depicted in the temperature records from 1756 to 1907, and the precipitation records from 1848 to 1907, Herr Otto Meissner finds a possible connection between these climatic features and the periodicity of sun-spots. In a table which he gives in No. 4533 of the *Astronomische Nachrichten* he arranges the years of the eleven-year period from 1 to 11, and opposite each gives the departures of the year's temperature and rainfall from the means. This indicates that the sun-spot maximum years are cold and wet, while the minimum years accord fairly well with the mean. A further investigation considering pressure is to be undertaken.

PROPOSED MEMORIAL TO PROF. P. G. TAIT.

ON Thursday last, November 30, a representative meeting of former students and friends of the late Prof. Tait was held at Edinburgh University, to consider the question of extending the memorials to him. His former colleague, Principal Sir William Turner, K.C.B., presided. About 150 apologies for absence were intimated, amongst these being expressions of approval and support from the Rt. Hon. A. J. Balfour, M.P., the Chancellor of the University; the Right Hon. Lord Aberconway; Sir Archibald Geikie, K.C.B., President of the Royal Society; Sir John Murray, K.C.B., and the Right Hon. Lord Haldane of Cloan, P.C. Lord Haldane wrote:—"I cannot be with you on the 30th, but I wish to say that I am very glad indeed that you are taking the step of raising a memorial fund in connection with Prof. Tait. The publication of his Life affords a suitable occasion for doing this. I shall be glad to be a contributor, for I feel that a record should be preserved of the regard in which his old students and the nation generally held this remarkable man. We have too few figures of the stature of Tait to let them pass away without endeavouring to keep a permanent memorial of their greatness."

As it is now almost a decade since Prof. Tait's death, his successor in the natural philosophy chair (Prof. J. G. MacGregor) made the following statement:—In explanation of the present state of this movement, it may be pointed out that Prof. Tait's main work can be divided into three portions: (1) his educational work, (2) his own experimental researches, and (3) his work in mathematical physics. An appropriate memorial might be raised in connection with any one or more of these. When he entered upon the work of the natural philosophy chair he was deeply impressed by the soundness of Prof. Tait's educational policy, and by the difficulties in the way of applying and extending it; and he suggested as a fitting memorial a fund which would make it possible to carry it out. Without the aid of any appeal, this suggestion led to the receipt of subscriptions to the amount of about 1500*l*. But before action could be taken, it was found that the University itself was organising, and could not defer, a general extension scheme. It was the unanimous opinion of those who had charge of this scheme that it would be unwise to carry on two competing movements at the same time; and the Tait memorial was for this reason made a department of the general extension scheme.

As such it could not be brought to the attention of old students and associates generally, but only to a comparatively small number of them. Nevertheless, additional subscriptions were made to the original fund to the extent of about 500*l*., and a special fund, yielding about 200*l*. per annum, was provided by Sir John Jackson, to be called Professor Tait's Memorial Fund, and to be used, under the direction of trustees, for research on the lines of Prof. Tait's experimental work.

There are thus memorial funds connected with two of the chief departments of Prof. Tait's activity, but none connected with the third.

The best form for a memorial connected with the professor's work in mathematical physics would obviously be a Tait chair in that subject; and Tait himself advocated the establishment of such a chair. In 1872 he wrote in an article in *Macmillan's Magazine*:—"Would it were not absolutely hoping against hope to proceed as follows. In the Scottish universities, let there be in each a professor of experimental physics and a professor of applied mathematics, in place of the present solitary professor of the enormous subject of natural philosophy."

Many old students have intimated that they would like to have the opportunity of contributing to a memorial. He was satisfied that a very large proportion of them would be found to share this feeling.

It will thus be seen that, as a Tait memorial has been founded, the question before this meeting is, shall we take for ourselves, and arrange to give to the whole body of the professor's students and associates and admirers, the opportunity of contributing towards the memorial, and, by enlarging the original fund, or founding a Tait chair, or in any other way that may be determined, making the memorial more worthy even than it now is of the man whose great work, personal and scientific, it is intended to commemorate?

On the motion of Mr. B. Hall Blyth, seconded by Sir G. M. Paul, a resolution agreeing to the proposal was carried.

A general and an executive committee were then appointed. Information will be willingly furnished by Prof. J. G. MacGregor, Edinburgh.

BIRD-NOTES.

IN the October number of *British Birds* another straggler is added to the British list—this time in the shape of the slender-billed curlew (*Numenius tenuirostris*), a small flock of which was observed towards the end of September, 1910, on Romney Marsh, Kent. Of these, an immature pair were shot on September 21, while an adult male was killed two days later. Two of them were examined in the flesh by Mr. M. J. Nicoll. Although stragglers have occurred in Heligoland, Holland, Belgium, northern France, and Germany, the slender-billed curlew is a native of the Mediterranean countries, whence it travels to Siberia to breed. Approximating in size to the whimbrel, the species is distinguished by its short and slender beak and the pear-shaped dark markings on the flanks. The colouring of the crown is unlike that of the whimbrel, showing black and buff streaks like those of the curlew.

In the same issue Dr. E. Hartert points out that English green woodpeckers differ from the central European representative of the species (*Picus viridis pinetorum*) by the still shorter and more slender beak, and on this character proposes that it should be recognised as a separate race (*P. v. pluvius*). Scandinavia, Russia, and eastern Prussia are the home of the typical race; the Italian form, on account of the beak being slenderer than in English birds, is named *P. v. fronus*, and the Spanish *P. v. sharpei* has long been recognised as distinct.

Most ornithologists, when pointing out the features in the plumage by which young partridges may be distinguished from old ones, content themselves with the statement that the tip of the first flight-feather of the wing is pointed in the former, but rounded in birds which have undergone their second autumnal moult. Dr. Louis Bureau, director of the Nantes Museum, in an article (in French) published in the October *Zoologist*, goes, however, much further than this. After stating that there are ten primary wing-quills, he observes that the tenth of the first plumage is the first to fall, this taking place about the end of the first month; when the replacing quill (second plumage) has attained a

length of about 15 mm.—which it does in three days—the ninth quill of the first plumage is moulted and replaced in a similar manner. After this the eighth, seventh, sixth, fifth, fourth, and third quills are successively shed and replaced, but at regularly increasing intervals, the rate of the development of their successors during twenty-four hours decreasing in the same order. The second and first quills are not shed at all during the first moult, but persist until the completion of the second moult, in September or October of the following year. This renders it possible to determine during a period of fifteen or sixteen months whether a partridge is young or old, the tip of the first quill being pointed up to that age and rounded subsequently. After this period age-determination by the plumage is impossible. The author adds that, by following the formula given above, the exact age of young partridges is determinable during the time that quill-moulting is in progress, although it has to be borne in mind that there may be a small "personal equation," some individuals moulting slightly in advance of, and others behind, their fellows.

In this connection it may be noted that *Country Life* of October 21 contains an article by the present writer on the breeding-ages of birds, in which attention is directed to the imperfect state of our knowledge on this subject.

The results of an expedition to the pheasant-countries of Asia are recorded by Mr. C. W. Beebe in the July issue (recently to hand) of the New York Zoological Society's Bulletin. It is stated that "this expedition, organised for the purpose of gathering original data for the preparation of a monograph of the pheasants, jungle-fowl, and peafowl, and made possible by the generous gift of Colonel A. R. Kuser, has been completed. The most sanguine expectations were exceeded in the amount of territory covered and the results attained. Voluminous notes have been taken, reinforced by a great number of photographs (some of which are reproduced in the article) and sketches, concerning the habits and ecology of the pheasants found in the countries visited, much of the material being new to science. Although the collecting of living birds was a secondary object of the expedition, several large shipments were sent back." In the same number it is stated that a female passenger-pigeon now in the Cincinnati Zoological Gardens is believed to be the last living representative of that once abundant species.

The need of a longer close season for the Australian stubble-quail (*Coturnix pectoralis*) is strongly urged by Mr. G. A. Keartland in the September number of *The Victorian Naturalist*. For a short time the close season was from August 1 to December 20; it was extended at different times to February 1, March 1, and April 1; but this year it has been put back to February 14, which the author urges is much too early, as many of the broods are then "cheapers." R. L.

THE SEVENTEEN-YEAR CICADA.

THE Cicadidæ are an interesting group of insects, which chiefly inhabit warm countries. They are represented in England by a small species (*Cicadetta montana*) which is almost confined to the New Forest, where it is scarce and local. In classical times they were known under the name of Tettix, and the loud stridulation of the males attracted much attention. As in England, so in the eastern United States, there is only one species which is common and well known, *Tibicina septendecim*, the peculiarity of which is that its life-cycle occupies seventeen years in the northern, and thirteen in the southern, States, and only at these intervals are they specially abundant. In America they are often improperly called locusts, and are reckoned among destructive insects, for the larva feeds on the roots of trees; and it is ranked among injurious insects.

The eggs are laid on the twigs of trees, and when the larvæ are hatched they drop to the ground and gather in clusters on the roots, from which they suck the sap. The pupa-state lasts only a few days, and when ready to emerge they form galleries, through which they ascend to the surface of the ground, and emerge, leaving their cast skins behind them. The perfect insect is easily recognisable, having a short, broad black body rather pointed at the hinder extremity, and four long and moderately broad wings with conspicuous reddish nervures, the fore wings being considerably larger and more pointed than the hind wings.

The Times of November 3 directs attention to the emergence of numbers of these insects during the last summer from the soil in the Bronx Zoological Park in New York; but when the writer adds, somewhat inconsequentially, "It is probable that the species is approaching extinction in view of modern conditions of cultivation, and the extension of building areas," we imagine that the contingency can hardly be so near as he supposes, although the complete extermination of once common insects in consequence of the changed conditions to which he refers is no uncommon occurrence. W. F. K.

SCIENTIFIC PROGRESS AND PROSPECTS.[1]

ALL advance in the relations between man and nature whereby man gains to any greater extent the mastery may be described as scientific progress; and in this connection we must recognise that many things which we now look upon, and have for ages regarded as entirely commonplace, were, at the time of their inception, really very remarkable indeed. Take, for instance, the application to human needs of fire. Animals, even of the highest types, make no use of it. There must have been a period when man also did not understand its properties, and, like the animals from which he has sprung, was afraid of it and left it severely alone. A time must next have come, and with that time the valorous man who first had the temerity to experiment with this very powerful and destructive agent.

Think of this prehistoric investigator into the means and effects of combustion in that far distant age; consider his inferior mental equipment; imagine his savage surroundings; take into account, also, his lack of any but the most primitive appliances. Must we not laud his enterprise and admire his courage? Must we not also acknowledge the enormous advantages his investigations have gained for all his posterity? The warming of their bodies and the cooking of both animal and vegetable nutriment would, no doubt, be the first uses to which our remote ancestors would apply the new agent; but soon would follow the firing of pottery, up to that date merely sun-baked, then the reduction and smelting of metals, and finally the whole galaxy of the arts. What is scientific progress if this is not? And yet it leaves off where what we usually mean by science begins, namely, about the Græco-Roman period. Look out, however, into London to-day, and recognise how little of all we see around us could have ever existed but for those early high-temperature experiments made so many thousands of years ago. Without them, could human beings even live in this northern climate?

Here may I point out that, curiously enough, it is only when we go back to the earliest evidences of primitive human life upon this planet that we take the true philosophical course of naming the periods we are dealing with after the main material advances in scientific progress made during those periods by the human race. We talk of the Stone age, of the Bronze age, or the Iron age, to denote those vast expanses of time during which the primitive inventor was discovering the means of applying new materials to what was then the great necessity of mankind, namely, weapons for the chase, for self-protection, and for war upon his enemies.

Later in history we find that this really philosophical method is abandoned. As we come to know more as regards the position, supremacy, and conditions of particular races, and still further when we become better acquainted with the deeds and achievements of particular individuals, we find that historians have a tendency to overlook the enormous influence of the results obtained by scientific investigators and discoverers, and to make it appear as though the current of events were really governed by those who, from accident of birth, official position, political influence, or martial achievements, have made for themselves reputations as leaders of men.

To see that this view is wrong we have only to survey the past. Can it for an instant be doubted that the labours of the unknown prehistoric individual to whom I have just

[1] From the presidential address delivered to the Röntgen Society on November 7 by Mr. A. A. Campbell Swinton.

alluded, who first discovered the properties of fire, or of those who originated the smelting of metals, who launched their frail, and at that time novel, coracles upon the ocean, and first applied wheels to the primitive cart, are more living factors to-day than the valour of all the warriors, the wisdom of all the statesmen, or the wiles of all the politicians that the world has seen? It is a truism, indeed, that the world knows little of its greatest men.

Can it be questioned that the discoveries of Archimedes and his disciples have more effect to-day than the battles of Alexander or of Hannibal? Or, if we turn to modern times, can it be gainsaid that Watt and Stephenson, Davy and Faraday, have done more to change both the course of history and the material conditions of life than did Napoleon or Wellington, Walpole or Pitt?

The fact is, as I once remember hearing lamented by no less a statesman than the late Lord Salisbury, that while the work of the politician, the statesman, the soldier, or the leader of men, however great and however fortunate, is of necessity but transitory, what is accomplished by one man being undone by another—the work of the scientific discoverer and inventor is everlasting. However insignificant this work may apparently be, provided it is new it adds something more to that great store of human knowledge and experience which is slowly accumulating, and enables man more and more to triumph over nature. Moreover, results that appear of but slender importance at the time of their discovery often turn out in the end to be of the greatest moment.

For the undue amount of influence on the progress of the world that is attributed to leaders of men, in comparison with that exerted by investigators of nature, historians are no doubt to blame. In stating this, however, one must in justice remember that, after all, most histories are written to sell, or, if not that, to bring fame to their authors. Further, we must allow that the story of scientific investigation is frequently not very interesting, at any rate to the general public, who may justly find such a story dull as compared with accounts of the stirring episodes that occur in the Senate or the feuds that are settled on the battlefield. Thus the tale of, say, Marlborough's campaigns makes probably more picturesque reading, and is more likely to interest the average student, than would be a history of the patient scientific work that led up, about the same period, to the enunciation, say, of Boyle's law of the expansion of gases. We can admit this, though there can be no doubt that the permanent influence of Boyle's discovery on the history of the world has been in the past, and will continue to be in still greater ratio in the future, incomparably greater than was that of all the battles of the day, inasmuch as Boyle's law was an important link in the chain of discoveries that led up to the steam engine and modern industrial development; while to-day the effects of the wars of the seventeenth century have, for all practical purposes, passed away.

The fact is that there is a glamour attached to the position of those who are supposed to direct the history of nations that prevents the real directing forces from being seen in their true proportions. The great statesment, the great generals, leaders of mankind in general, are, after all, nothing much more than glorified policemen, whose utility to the world is only occasioned by the imperfections of human nature. As organisers they are no doubt useful, but they generally benefit particular nations at the expense of others; and, as a rule, they leave little behind them that will stand the test of centuries.

Another product of human endeavour which also seems to have an undue amount of importance attached to it in regard to its influence on human progress is literature, which I am here considering apart entirely from its æsthetic claims upon us as a means of relaxation. That literature has a directive influence, and that a powerful one, no one can deny; but I fancy that all scientific men will agree that it is not to be compared with that exercised by material discoveries and inventions. In saying this, I know that it is the fashion to ascribe the beginning of all modern science to what is contained in the "Novum Organum"; but I rather fancy that if we could truly estimate the influence on the world's history of the two men, we should find that Roger Bacon, the inventor of gunpowder, would come before the better known Francis Bacon, who, some centuries later, wrote his great work on the new learning. Indeed, probably the chief merit of the "Novum Organum" was that it assisted a return to experimental methods as opposed to what had become the benumbing system of Aristotle, who, by the way, is interesting to this society for the reason that he was the author of the immortal, if not very illuminating, phrase that "nature abhors a vacuum." Anyway, since the earliest times there has never been a better organised and more successful mutual admiration society than that formed by the writers of the world, who have always been chiefly concerned to discuss one another and one another's scripts. This, and the fact that the written word endures, has given to the wielders of the pen a prominence in history to which they are scarcely entitled by their influence on progress.

At the present time, when it is the fashion to ascribe the production of all wealth to the manual labourer and all progress to the politician, it is more than ever necessary that correct views should be insisted on. Let us, therefore, emphasise the fact that from the beginning of the world all advance has been due, not to the many, but to a few exceptional individuals; and had it not been for the genius of these we should still be naked savages, not even painted with the proverbial woad.

As an instance, take the electric telegraph, which has had more effect on civilisation than almost anything else during the past century, and gives employment to thousands. The names of those to whom it is due, beginning with Franklin, Volta, and Galvani, going on with Morse and Cook, and ending with, say, Wheatstone and Kelvin, can literally be counted upon one's fingers. Nor is it very different with the steam engine or with the railway itself, which, to read some of the newspapers of to-day, one would almost think had been invented by the rank and file of the railway workers.

Most really scientific workers feel that knowledge for knowledge's sake is a sufficiently worthy object for pursuit, and are content with the extension of knowledge and the satisfaction that it brings without immediately desiring precise information as to the practical results that are likely to follow from any particular line of investigation. It is well that this is so, as otherwise many of the lines of scientific research that have been most fruitful in bringing lasting benefits to mankind would never have been begun or followed up.

As an instance of this, could there be a better example than the history of that most remarkable and important discovery in physics which was the primary cause of the foundation of this society?

Consider for a moment the position of affairs many years ago, when Sir William Crookes first commenced his laborious experiments on the electric discharge through rarefied gases. Could anything be imagined of more purely academic interest, and, at the time, seemingly less likely to lead to results of a practical nature? The small scale, the extreme delicacy of the apparatus, the uncertainty of the results, the minuteness of the forces involved, all tended to give to the investigations an air so entirely aloof from the practical concerns of everyday life that one can scarcely wonder that for years it was only a few of the very foremost scientific intellects who had sufficient insight to take much interest in the matter.

Yet we all know how things have turned out; how, as a direct result from these very recondite investigations, we have had the discovery of the Röntgen rays, with their practical applications to the investigation of the human frame, to the relief of suffering, and to the cure of disease; and also, as another result, perhaps the most momentous and far-reaching upheaval in scientific thought on the constitution of matter and the nature of electricity that has taken place for centuries, heralding the birth of a new idea, that of radio-activity, which may in future be destined to prove the salvation of the whole human race from annihilation. Here, of course, I refer to the vast and previously unsuspected source of energy that modern investigations have shown to lie hidden away in the atoms of matter, a store which is revealed by the energy given out by radium and other radio-active substances, and one which we may hope to see made available for human use in centuries to come, when others, such as those contained

n the coal and oil of the earth, at present being exploited, re exhausted.

So far as I am aware, the results of modern discovery ave had no effect in weakening our belief in the truth of he great principle of the conservation of energy as defined n what is commonly called the first law of thermodynamics, which law is really a statement that the sum f energy in the universe, just as the amount of matter, s a constant, and cannot be either increased or diminished y any means whatever.

When, however, we come to the so-called second law, which, as stated by Clausius, is that it is impossible for a elf-acting machine, unaided by external agency, to convey eat from one body to another at a higher temperature, r, as given by Lord Kelvin in a somewhat different form, hat it is impossible by means of inanimate material gency to derive mechanical effect from any portion of natter by cooling it below the temperature of the coldest f the surrounding objects, we find that even the authors f these statements are prepared to admit that this second aw stands on a totally different basis from the first law, nd, as declared by Maxwell, can only be said to be tatistically correct, or correct only when we are dealing vith masses of matter and not with individual molecules.

Indeed, it was in this connection that Maxwell propounded his celebrated proposition, in which he supposes hat a demon who could see individual molecules, and was ossessed of superhuman dexterity, could open and close n aperture in a partition dividing a vessel into two eparate portions, A and B, so as to allow only the swifter nolecules to pass from A to B, and only the slower ones rom B to A, in which case, without the expenditure of vork, the temperature of B would be raised and that of A lowered, in contradiction to this second law.

It will further be observed that in the definitions quoted bove Clausius is careful to qualify his statement by words o the effect that there must be no external aid, while ord Kelvin is even still more specific, and expressly limits he whole law to things inanimate.

Now lately, in London, we have had—I suppose s the result of Prof. Bergson's remarkable writings—one f the usual periodic outbreaks of more or less metaphysical discussion, and, incidentally, there has been raised uite seriously the question as to whether living organisms re subject to these laws of thermodynamics or not.

So far as the first law is concerned, there seems to be omplete agreement that there can be no question of any ut an affirmative reply, as we can scarcely suppose living hings to be capable of creating energy any more than of reating matter.

But when we come to the second law there are apparntly those who hold that it is different—who, in fact, elieve that there is good reason for doubting whether this econd law, which prevents us by the use of any mere nachine from getting mechanical effect from the general tock of heat, applies to living organisms at all. Indeed, n the contrary, it is contended that it is probable that, n the case of certain animate bodies, this is actually being ccomplished all the time; in other words, that there exist ving things which in some fashion or other do very much hat was the business of Maxwell's demons to do, and in his manner extract the energy that they require from the eneral stock. Here, obviously, is a most important natter for investigation, and one, having regard to its ombined physiological and physical aspects, peculiarly dapted to be tackled by the members of the Röntgen ociety, that is to say, if those who put it forward can nake out a sufficient case to make actual experiment orth while.

The interest of the question will be especially apparent o anyone who has seen the so-called Brownian movements hich can be perceived by ultramicroscopic methods in nely divided solid matter, such as particles of colloidal old suspended in a liquid or of tobacco smoke in a gas. hese movements are now believed to be due to the actual ostling of the minute particles by the moving molecules hemselves, and give the most wonderful notion of the easeless state of agitation that exists among the molecules f all substances at any temperature above that of the ltimate zero, and the vast amount of energy that is stored n these perpetual movements.

Indeed, so remarkable do the Brownian movements appear that their original discoverer, who detected them in finely divided vegetable matter, came to the conclusion that the particles were alive.

To return to the main question, however, without presuming to pronounce any opinion one way or another on the very startling idea that living matter is not always subject to the second law of thermodynamics, but finds means, in some cases at all events, to evade its provision, I desire to direct attention to the stupendous consequences that would follow could such a view be established. Here, at last, we should have the equivalent of the perpetually burning lamp of the story books, which consumed no oil; the perpetual fire of the burning bush, which required no fuel. We should have immediately to hand the means of producing the perpetual motion dreamed of by mediæval philosophers. We should only have to cultivate the right kind of organisms in sufficient masses, and they would do all this for us. Moreover, there would be nothing lost; the heat that was thus accumulated locally for our needs would dissipate itself again into the common store, as would also the mechanical effects after they had done their work. The unordered molecular motions of which the Brownian movements give us an indication—motions which constitute heat—would merely be directed for a time in the particular manner needful to give us the power that we require. Life would be the directing force; but it would be a directing force only, and would do no work.

It is a fascinating prospect, giving us a glimpse of what some may perhaps think is destined to take the place of fuel a few hundred years hence, when the latter is all exhausted and before means have been found to unlock the still greater stores of atomic energy that have already been alluded to. To those, however, who have been brought up to rely on the orthodox doctrines of thermodynamics, it seems not only very revolutionary, but also very heterodox from a physical point of view. Personally, as one totally ignorant of biology, I am only here concerned to point out the inevitable consequence of admitting that living matter is not subject to the second thermodynamic law, a proposition which I venture to believe has never before now been put forward seriously in any responsible quarters.

Among the many scientific problems that await solution, problems which, if satisfactorily solved, would have an enormous effect on the habits of mankind, is that of distant electric vision, or the power to see objects a great way off by electrical means; in other words, to do for the sense of sight what the telephone has done for the sense of hearing. Indeed, if this extension of our sense of vision was obtained, we could well afford to dispense with any extension of our other senses, namely, those of taste, smell, and touch, the senses of sight and of hearing being, for all ordinary purposes, much more important to us than are the others.

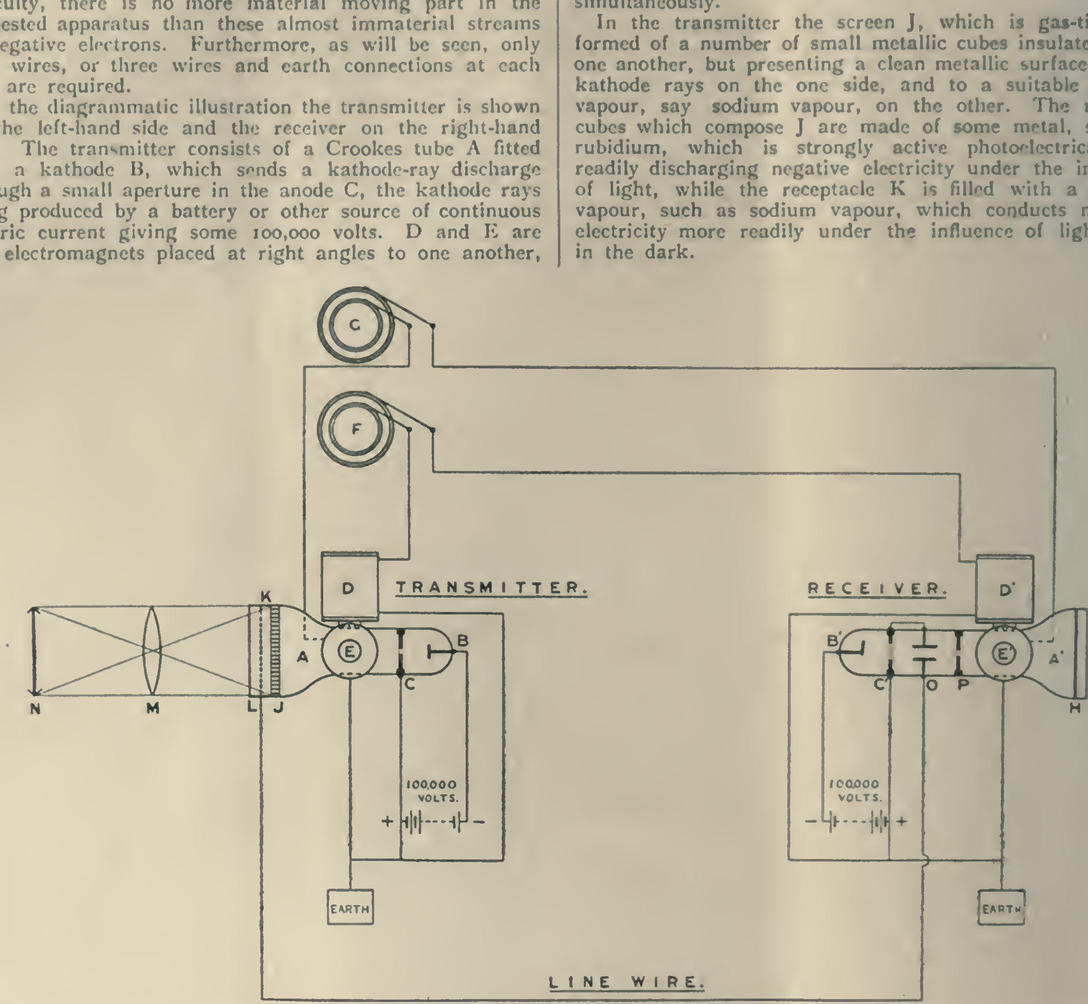
So long ago as the year 1908, in connection with a paper published in NATURE by the late Mr. Shelford Bidwell, I wrote a letter in that journal suggesting that the difficulty of obtaining the necessary enormous numbers of synchronised operations per second could possibly be solved by the employment of two beams of kathode rays, one at the transmitting and one at the receiving station, sychronously deflected by the varying fields of two electromagnets placed at right angles to one another and energised by two alternating electric currents of widely different frequencies, so that the moving extremities of the two beams would be caused to sweep synchronously over the whole of the required surfaces within the one-tenth of a second necessary to take advantage of visual persistence; and that, so far as the receiving apparatus was concerned, the moving kathode beam would only have to be arranged to impinge on a sufficiently sensitive fluorescent screen, and, given suitable variations in its intensity, to obtain the desired result. As, since that date, I have several times been asked to explain more in detail this idea, I now propose to do so, though it must be distinctly understood that my plan is an idea only, and that the apparatus has never been constructed. Furthermore, I would explain that I do not for a moment suppose it could be got to work without a great deal of experiment, and probably much modification. It is, indeed, only an effort of my imagination, and can be useful merely as a suggestion of a direction in which

experiment might possibly secure what is wanted. What, however, is claimed is that, so far as I am aware, it is the first suggested solution of the problem of distant electric vision in which the difficulty of securing the required extreme rapidity and accuracy of motion of the parts is got over by employing for these parts things of the extreme tenuity and weightlessness of kathode rays. Indeed, apart from the revolving armatures of the alternators employed for synchronisation, which present no difficulty, there is no more material moving part in the suggested apparatus than these almost immaterial streams of negative electrons. Furthermore, as will be seen, only four wires, or three wires and earth connections at each end, are required.

In the diagrammatic illustration the transmitter is shown on the left-hand side and the receiver on the right-hand side. The transmitter consists of a Crookes tube A fitted with a kathode B, which sends a kathode-ray discharge through a small aperture in the anode C, the kathode rays being produced by a battery or other source of continuous electric current giving some 100,000 volts. D and E are two electromagnets placed at right angles to one another,

Similarly, in the transmitting apparatus, the kath[ode] rays fall on a screen J, the whole surface of which t[hey] search out every tenth of a second under the influence [of] the magnets D and E. Further, it is to be remarked th[at] as the two magnets D and D′ and the two magnets [E] and E′ are energised by the same currents, the movem[ents] of the two beams of kathode rays will be exac[tly] synchronous, and the kathode rays will always fall on the two screens H and J on each corresponding sp[ot] simultaneously.

In the transmitter the screen J, which is gas-tight, [is] formed of a number of small metallic cubes insulated fr[om] one another, but presenting a clean metallic surface to the kathode rays on the one side, and to a suitable gas or vapour, say sodium vapour, on the other. The metal cubes which compose J are made of some metal, such as rubidium, which is strongly active photoelectrically [in] readily discharging negative electricity under the influence of light, while the receptacle K is filled with a gas or vapour, such as sodium vapour, which conducts negative electricity more readily under the influence of light than in the dark.



which, when energised by alternating current, will deflect the kathode rays in a vertical and in a horizontal direction respectively.

The receiving apparatus consists similarly of a Crookes tube A′ fitted with a kathode B′, which, in circumstances to be further described, transmits kathode rays through an aperture in the anode C′. D′ and E′ are two electromagnets placed at right angles, similar to those in the transmitter, the two magnets D and D′, which control the vertical motions of the kathode-ray beam, being energised from the same alternating dynamo F, which has a frequency, say, of ten complete alternations per second; while the other two magnets E and E′, which control the horizontal movements of the kathode-ray beam, are energised by a second alternating dynamo G having a frequency of, say, 1000 complete alternations per second.

In the receiver H is a fluorescent screen, upon which, under conditions to be further described, the kathode rays impinge, and the whole surface of which they search out every tenth of a second under the combined deflecting influence of the two magnets D′ and E′, with the result that under these conditions the screen fluoresces with what appears to the eye as a uniform brilliancy.

Parallel to the screen J is another screen of metalli[c] gauze L, and the image to be transmitted of the object [N] is projected by the lens M through the gauze screen L [on] to the screen J through the vapour contained in K. The gauze screen L of the transmitter is connected throu[gh] the line wire to a metallic plate O in the receiver, p[ast] which the kathode rays have to pass. There is, furth[er,] a diaphragm P fitted with an aperture in such a positi[on] as, having regard to the inclined position of B′, to cut o[ff] the kathode rays coming from the latter and prevent them from reaching the screen H unless they are slightly repell[ed] from the plate O, when they are able to pass through the aperture.

The whole apparatus is designed to function [as] follows:—

Assume a uniform beam of kathode rays to be passi[ng] in the Crookes tubes A and A′, and the magnets D and [E] and D′ and E′ to be energised with alternating current, a[s] mentioned. Assume, further, that the image that is desire[d] to be transmitted is strongly projected through the lens [M] through the gauze screen L on to the screen J. Then, a[s] the kathode rays in A oscillate and search out the surfac[e] of J, they will impart a negative charge in turn to all th[e]

metallic cubes of which J is composed. In the case of cubes on which no light is projected, nothing further will happen, the charge dissipating itself in the tube; but in the case of such of those cubes as are brightly illuminated by the projected image, the negative charge imparted to them by the kathode rays will pass away through the ionised gas along the line of the illuminating beam of light until it reaches the screen L, whence the charge will travel by means of the line wire to the plate O of the receiver. This plate will thereby be charged; will slightly repel the kathode rays in the receiver; will enable these rays to pass through the diaphragm P, and, impinging on the fluorescent screen H, will make a spot of light. This will occur in the case of each metallic cube of the screen J, which is illuminated, while each bright spot on the screen H will have relatively exactly the same position as that of the illuminated cube of J. Consequently, as the kathode-ray beam in the transmitter passes over in turn each of the metallic cubes of the screen J, it will indicate by a corresponding bright spot on H whether the cube in J is or is not illuminated, with the result that H, within one-tenth of a second, will be covered with a number of luminous spots exactly corresponding to the luminous image thrown on J by the lens M, to the extent that this image can be reconstructed in a mosaic fashion. By making the beams of kathode rays very thin, by employing a very large number of very small metallic cubes in the screen J, and by employing a very high rate of alternation in the dynamo G, it is obvious that the luminous spots on H by which the image is constituted can be made very small and numerous, with the result that the more these conditions are observed the more distinct and accurate will be the received image.

Furthermore, it is obvious that, by employing for the fluorescent material on the screen H something that has some degree of persistency in its fluorescence, it will be possible to reduce the rate at which the synchronised motions and impulses need take place, though this will only be attained at the expense of being able to follow rapid movements in the image that is being transmitted.

It is further to be noted that as each of the metallic cubes in the screen J acts as an independent photoelectric cell, and is only called upon to act once in a tenth of a second, the arrangement has obvious advantages over other arrangements that have been suggested, in which a single photoelectric cell is called upon to produce the many thousands of separate impulses that are required to be transmitted through the line wire per second, a condition which no known form of photoelectric cell will admit of.

Again, it may be pointed out that sluggishness on the part of the metallic cubes in J or of the vapour in K, in acting photoelectrically, in no wise interferes with the correct transmission and reproduction of the image, provided all portions of the image are at rest; and it is only to the extent that portions of the image may be in motion that such sluggishness can have any prejudicial effect. In fact, sluggishness will only cause changes in the image to appear gradually instead of instantaneously.

Many modifications are, of course, possible in detail. For instance, the plate O of the receiver might perhaps better be replaced by an electromagnet or solenoid so arranged as to repel the kathode beam when energised. Again, the somewhat crude form of photoelectric cell described, composed merely of insulated cubes of rubidium in contact with sodium vapour, might be improved upon. Indeed, it is highly probable that research will reveal much more sensitive materials, the use of which would vastly improve this part of the apparatus, which at present is probably the one least likely to give the desired results.

GEOGRAPHY OF BRITISH CENTRAL AFRICA.[1]

ATTENTION was first directed to "British Central Africa" by Dr. Livingstone in 1859. By the term "British Central Africa" I mean the present protectorate of "Nyasaland," together with north-eastern Rhodesia; that is, the British territory bordering on the Shire River, and on Lakes Nyasa, Tanganyika, Mweru, and Bangweulu.

Records show that the Portuguese had some knowledge of the Nyasa regions so far back as the seventeenth century, though they never established any stations there. They followed the line of "least resistance," the Zambezi River, which was navigable for small craft up to the Kebrabasa rapids. It may be taken as practically certain that at the very ancient period when at "Zimbawe" and elsewhere in Mashonaland there existed a flourishing gold-producing industry, the River Zambezi was known and navigated by the same ships which brought traders to the port of Sofala. No ancient rock-workings for gold have been found north of the Zambezi similar to those in Mashonaland, but it is not improbable that the traders of those days obtained copper from Katanga, and used the Zambezi as their most available transport route. With regard to the ruins in Mashonaland, no African race unaided ever erected these stone buildings, nor, in my opinion, can they be dated back to anything but the most ancient times. The idea that Solomon got his gold there has sometimes been ridiculed; but why not? We know that in those times fleets were sent out from the Red Sea periodically, which returned with gold, apes, ivory, and feathers—all products of Africa. These ships were probably identical with the Red Sea dhows of to-day. Where would explorers with vessels of that type be likely to go first, on leaving the Red Sea? Out into the Indian Ocean? or down the African coast? They would, of course, follow down the land; and whether or not in King Solomon's days he got his gold from the east or the south, it may be taken as certain that the whole East African coast was then known and frequented by traders. It is interesting to note that the question as to who were the ancient people who worked the gold-mines of South-east Africa is no new one. In that fascinating book, "A History of Africa," by John Ogilby, published in 1670, the matter is thoroughly discussed, and the arguments for and against King Solomon are fairly stated. Ogilby says, in speaking of the kingdom of Monomotapa: "In this country far to the inland on a plain stands a famous structure called Zimbawe, built square like a castle with hewn stones of a wonderful bigness. Above the gate appears an inscription which cannot be read or understood, nor could any that had seen it know what people used such letters. Near this place are more such buildings by the same name, signifying a court or palace. The inhabitants report it a work of the devil, themselves only building with wood." Also, as regards Sofala, he says: "The inhabitants aver that this is the very true Ophir from whence King Solomon had his gold." Then follows a full statement of the arguments *pro* and *con*.

The geographical position of Nyasaland is a somewhat remarkable one. The Shire valley and Nyasa form the southern portion of one of the greatest "rifts" in the African continent. This depression, after a break north of the lake, is carried on for 400 miles by Lakes Rukwa and Tanganyika, and, with a few short breaks, runs on by Lakes Kivu, Albert Edward, and Albert, to the Nile valley. Following this route, a journey by boat could be made from the mouth of the Zambezi to the Mediterranean, a distance of more than 4500 miles, covering 50 degrees of latitude, with a total distance of land portages of not more than 500 miles. A curious point about this great line of depression is that for a great part of its length it lies almost alongside the backbone of tropical Africa, the watershed in some parts approaching within a few miles of the lakes which lie along its course.

Most of British Central Africa has an average elevation of some 3000 to 4000 feet above sea-level. Here and there are higher plateau masses and peaks, which in some cases rise to close on 10,000 feet. The most notable of these plateaux are "Nyika" in the North Nyasa district and "Mlanje" in the Shire Highlands. The former has an average altitude of 7000 to 8000 feet with an area of 2000 square miles, and a European climate; the Mlanje plateau lies at 6000 to 7000 feet, and has an area of some 250 square miles. Both are what Sir Harry Johnston used to call "Jack and the Beanstalk" countries, the plateau sides rising precipitously from the surrounding country, and being almost unclimbable. On Mlanje grows the *Widdringtonea whytei* (Mlanje cypress), a large handsome conifer, a very valuable timber of excellent quality, durable and impervious to the attacks of white ants.

[1] From a paper on "The Geography and Economic Development of British Central Africa," read before the Royal Geographical Society on December 4, by Sir Alfred Sharpe, K.C.M.G., C.B.

British Central Africa is drained (*a*) by the Nyasa-Shire-Zambezi outlet, (*b*) the Loangwa-Zambezi, (*c*) the Luapula-Congo. That portion of the Nyasa-Tanganyika plateau which borders on the route of the "Stevenson road" drains in five directions: (1) To Lake Tanganyika and the Congo, (2) to Nyasa, (3) to the Chozi and Luapula, (4) to Lake Rukwa, which has no outlet, (5) to the Loangwa and Zambezi.

But while the bulk of this portion of Africa lies at elevations over 3000 feet, the two main drains to the south, Nyasa-Shire and Loangwa-Zambezi, form deep depressions of considerable width, not attaining an altitude of anything above 1500 feet in their northernmost (highest) parts. One result of this is that British Central Africa has two climates, that of the low country, hot and somewhat unhealthy, and that of the uplands, pleasant and fairly healthy.

When I first knew Nyasaland, in 1887, there was an available line of water transport some 700 miles in length from the Zambezi mouth to the north end of Lake Nyasa, with one break only, the Murchison cataracts of the Shire River (which extend for some 40 miles). During recent times the course of the Shire has so rapidly and persistently silted up, both above and below the cataracts, that at the present day the upper portion is almost unnavigable at any season, and the lower river, instead of being available as a transport route all the year round from the sea to the foothills of the Shire Highlands, can only be used for a few months of the year so far as the junction with the Ruo River. The Shire gathers very little water on its course, and is the overflow pipe from the Nyasa tank. When that tank almost ceases to overflow, as is the case at present, the pipe *must* be more or less empty, and no human power can fill it.

This enforced abandonment to a great extent of the Shire as a transport route has been a terrible handicap on the growing planting industries of Nyasaland, which at this moment is unable to find a means of transporting to the sea-coast the cotton, tobacco, rice, maize, tea, rubber, and other marketable articles she is actually producing. The suggested extensions of the railway north and south will enable the protectorate not only to deal with what she is now producing, but to open up large additional tracts of land.

For the present fall in level of Lake Nyasa, the result of which is a far scantier and only intermittent overflow into the Shire River, it is difficult to assign any reasonable cause except a decreased rainfall in the basin; but such observations and records as have been kept at lake stations during the last few years do not seem altogether to bear out this supposition. A theory which might to some extent account for definite cycles of rise and fall of the level of Nyasa (presumably due to lessening and increasing rainfall) has suggested itself to me, and I advance it for what it is worth. We are aware that Tanganyika has a natural outlet to the Congo. When Livingstone and Stanley were there this outlet was found (the Lukugu), but it was blocked up; it was clear from native evidence that the lake had been rising in level for a number of years. The prophecy was then made that sooner or later it would break out at its old outlet. This subsequently took place, and for years Tanganyika has sent its surplus waters to the Atlantic. I am not aware whether the Lukugu has yet closed again. A noticeable feature on Nyasa is an old beach-mark, 6 or 8 feet above the highest level to which the lake now rises. This mark is distinct and clear, especially on the rocks, and is carried round the lake both in the open and in the most secluded and sheltered bays. It is abundantly evident that at some not very distant time the lake had this higher level, from which there must have been a *sudden* fall. Some few years ago, during the dry season, Nyasa ceased to overflow, and the bed of the Shire River at its exit began to silt up, reeds and other plants took root, and natives were able to walk across with only a few inches of water here and there. It would only have needed a few similar seasons for the outlet to have become entirely choked up, as was the case with the Lukugu. Is it not probable, therefore, that this has actually taken place at previous periods, and that the level of the lake subsequently rose until it overflowed the barrier and finally burst it? Is it not, moreover, probable that these cycles of fall, blocking up, rise, and outburst have been going on for ages? A sort of recurring decimal.

The Nyasaland basin is very limited in extent. The bulk of the water which enters the lake comes in at its northern end from high country lying beyond the Anglo-German boundary. Part of this country consists of a very interesting volcanic district in "Kondeland," which is dotted over with the craters of extinct volcanoes. On the east side of Nyasa the watershed between the lake and the Indian Ocean lies within a few miles. No rivers of any size enter the lake from the east.

To refer to the climate of British Central Africa. Throughout the higher levels, from May to September inclusive, it would be hard to find a pleasanter climate. October and November are hot, but dry; December to March constitutes the rainy season; April is cool and finer (the finishing of the rains). Malaria is, of course, the chief trouble. If this could be checked there is no reason why the elevated plateaux, not only of British Central Africa, but of many other parts of tropical Africa, should not be as healthy as Queensland. Knowledge which has been gained during the last ten years, largely through the exertions of the London and Liverpool Tropical Schools of Medicine, has enabled us not only to get a very much better insight into the causes of malarial fevers, but also to some extent to prevent their occurrence. Most tropical diseases are now known to be communicated by various biting insects, and if it were possible to protect ourselves against the attacks of these we should be able to prevent fevers. The difficulty, however, is to carry this out successfully.

A few years ago the first cases of sleeping sickness were discovered in British Central Africa. The disease reached this part of the continent from the Congo State, having, no doubt, been carried to the shores of Tanganyika and Mweru, and to the Luapula Valley, by the numerous expeditions from the Congo to the eastern boundaries of the Free State. It quickly established itself on Tanganyika and Mweru and in the Luapula Valley, also along the banks of several of the larger rivers running into Mweru and Tanganyika. Quite recently cases have appeared in the valley of the Luangwa, and also in the country bordering on the south-western shores of Lake Nyasa; and it is evident that there is in this part of Africa some hitherto unknown agent which carries the germ of sleeping sickness, as the tsetse-fly known as *Glossina palpalis* does not exist in the protectorate of Nyasaland (although it is found on Lakes Tanganyika and Mweru). More than one expedition is now at work investigating these interesting questions, and especially as regards the connection between tsetse-fly and big game. Whatever the results obtained by these expeditions may be, however, it is, I think, already evident that sleeping sickness will not prove to be such a scourge in these parts as it has been in Uganda.

It has been believed by many that the presence of game, and especially buffalo, is responsible for the existence of tsetse-fly. After many years spent in travelling over every part of Nyasaland and much of northern Rhodesia, Portuguese and German East Africa, and the Upper Congo, I arrived at the conclusion that the weight of evidence is against this theory, so far as tropical Africa is concerned; and in this belief, namely, that *tsetse in these regions does not depend on big game for its existence*, I think that all who are entitled to speak with authority, including Mr. Selous, are now agreed.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE annual prize distribution and students' conversazione of the Northampton Polytechnic Institute, Clerkenwell, E.C., will be held to-morrow, December 8. Sir William H. White, K.C.B., F.R.S., will distribute the prizes and certificates.

THE organising committee for the Imperial University Congress to be held in London next July has appointed Dr. Alexander Hill, formerly Master of Downing College, Cambridge, to be secretary to the congress, in succession to the late Dr. R. D. Roberts.

A STUDY of the calendar for the session 1911–12 of the University College of North Wales emphasises how much has been accomplished in recent years in making more easily available the advantages of higher education. It can no longer be said that university education is possible only for the child of wealthy parents. The present calendar shows that the fees of an ordinary arts student at the University College of Bangor amount only to 13*l.* 1*s.* per session, and of a science student to 17*l.* 1*s.* per session. The total cost of living in lodgings and tuition in Bangor averages from 35*l.* to 45*l.* for the session.

THE annual meeting of the trustees of the Carnegie Foundation for the Advancement of Teaching was held in New York on November 17. According to a Press notice, says *Science*, Mr. Carnegie gave 200,000*l.* of the 1,000,000*l.* which he had promised in case the State-supported institutions were admitted to the benefits of the foundation. The endowment is 2,425,200*l.*, yielding an annual income of 118,000*l.* Last year, it is said, the sum of 105,200*l.* was paid for pensions to 370 professors and widows of professors. Forty-eight were added to the list for the year, and fifteen died. The University of Virginia was added to the list of accepted institutions.

THE fourth annual dinner of the old students of the Royal College of Science, London, will be held at the new Imperial College Union, Prince Consort Road, South Kensington, on Wednesday, December 13. Sir Alexander Pedler, F.R.S., president of the Old Students Association, will preside; and the guests will include the President of the Board of Education, the Rt. Hon. A. H. D. Acland, Sir Robert Morant, K.C.B., Sir Arthur Church, K.C.V.O., Sir Alfred Keogh, K.C.B., Prof. S. H. Cox, and Prof. W. E. Dalby. Tickets for the dinner may be obtained on application to the secretary of the Old Students Association, 3 Selwood Place, S.W.

IT was proposed recently that steps should be taken to establish a University of Brighton, and a meeting is to be held on Tuesday next, December 12, by invitation of the Mayor of the town, to consider the subject. It is suggested that there might be affiliation with the Municipal College at Portsmouth and the Hartley University College, Southampton, to constitute a new university for the South Coast, or that the present radius of the University of London should be extended to include the proposed new University College. Hitherto, Brighton has not shown any very marked desire to take a prominent part in technical or university education. The town has a population of 131,000, yet there are only between sixty and seventy day students in the Municipal Technical College, and nearly two-thirds of these are first-year students. This does not provide a very promising nucleus upon which to constitute a university or a university college, or indicate keen local interest in higher education. We should be sorry, however, to discourage the proposal, and we trust that next Tuesday's meeting will lead to the formation of a scheme which will be successfully carried out in due course.

THE report of the council of the Royal Agricultural Society, adopted at the annual general meeting held yesterday, contains, among other interesting particulars, information concerning certain alterations in the regulations and syllabuses of the society's examination in agriculture. The National Agricultural Examination Board is of opinion that the time has arrived when the practice of examining in elementary science might be discontinued, and the subjects of examination will in future be:—practical agriculture (two papers), farm and estate engineering (including surveying, buildings, machinery, and implements), agricultural chemistry, agricultural botany, agricultural book-keeping, agricultural zoology, and veterinary science. Candidates will have the option of taking the whole eight papers in one year, or of sitting for a group of any four in one year, and the remaining group of four in the next year. In order to be eligible to sit for the new examination, a candidate must present a certificate from a recognised agricultural college that his attainments in the subjects of general botany, general chemistry, geology, and physics and mechanics, as attested by class and other examinations, are, in the opinion of the authorities of the college, such as to justify his admission to the examination.

So much attention has been directed during the year to the question of the legitimate place of public examinations in our system of education that a special interest is attached to an unsigned article in the Journal of the Royal Society of Arts of November 10 on the number of candidates offering themselves for the public examinations held during the year 1910. It appears that some 300,000 pupils were examined, without counting students presenting themselves for university and professional examinations and all the competitive examinations for the Army, Home and Indian Civil Services, and so on. This very large total included about 23,000 candidates in each case for the Local examinations held by the Universities of Oxford and Cambridge, some 6000 for the London Matriculation examinations, about 113,500 for the science and art examinations of the Board of Education, 24,500 for the technological examinations of the City and Guilds of London Institute, 11,500 for the London Chamber of Commerce examinations, 9000 for those of the College of Preceptors, about 14,500 for those of the National Union of Teachers, 42,000 for the examinations of the Lancashire and Cheshire Union of Institutes, and more than 27,000 for those of the Royal Society of Arts. As the writer of the article remarks: "Most people will admit that, whether examinations are or are not desirable, the thing is somewhat overdone."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 23.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir Norman **Lockyer**: The iron flame spectrum and those of sun-spots and lower-type stars. Previous publications are referred to indicating that the spectral lines of the metallic elements have been separated into two series, one seen best in the hotter stars and when high temperature and great electric energy are employed. These were termed "enhanced lines." The other set, existing in stars of the solar type, but not in high-temperature stars, and seen with lower degrees of heat and electric energy in the laboratory, were called "arc lines." These lines have been shown to be strengthened in sun-spot spectra, while the enhanced lines are weakened. It seemed important to consider as a third term the spectrum given by the comparatively low temperature of the oxyhydrogen flame and see how the lines in the spectrum behave in the spectra of sun-spots and lower-type stars. Photographs have been recently obtained of the oxyhydrogen flame spectrum of iron, using greater dispersion than has hitherto been employed on that spectrum at Kensington. It has been found that the lines existing in the flame spectrum nearly all behave in a similar way in sun-spot spectra, these lines being extensively winged in passing from the Fraunhoferic spectrum to the sun-spot spectrum, and, generally speaking, more conspicuous in the latter. It has also been found that the flame lines are just those which are relatively strong in the electric furnace spectra of iron, the spectrum furnished by the lowest temperature conditions dealt with in the furnace being almost identical with the oxyhydrogen flame spectrum. With regard to the behaviour of the flame lines in the spectra of lower-type stars, it is found that in the region λ 4000 to λ 4330 they are mainly unaffected in the spectrum of Arcturus. In the region λ 4330 to λ 4500 the evidence tends to show that most of the lines are strengthened both in Arcturus and α Orionis, but this point cannot be definitely established until stellar spectra of greater dispersion are available.—Sir Robert **Hadfield**: Sinhalese iron of ancient origin. There being little definite evidence regarding ancient iron, the author describes some specimens from the buried cities of Ceylon. His paper supplements one by Dr. G. Pearson, read to the society in 1795, on Indian steel of modern manufacture. The specimens investigated, obtained through the kindness of the Governor-General of Ceylon, Sir Henry McCallum, are (1) a steel chisel, fifth century A.D.; (2) an ancient nail, probably of same place and date; (3) a bill

hook. This date has been verified by Dr. A. Willey, F.R.S. Examination of the chisel showed—

Composition:	C	Si	S	P	Mn	Fe	Specific gravity.
	traces	0·12	0·003	0·28	nil	99·3%	7·60

Difference being slag and oxide.

Frémont shear test showed 16 tons per square inch elastic limit, 26 tons per square inch breaking load. Shock test showed 17 kg. with 85° bend before breaking. Brinell ball test showed hardness numbers 144 and 144 on opposite sides. Scleroscopic hardness, 35. Transverse section shows the specimen to be somewhat carbonised, with carbonised areas on two sides. The presence of martensite and hardenite suggests the important information that the chisel was quenched. The analyses in the paper probably represent the only modern complete determination of the composition of authentic specimens of ancient iron. The percentage of phosphorus, though high, does not greatly differ from modern bar iron. Sulphur is extremely low, showing the employment of a very pure fuel. There is very little silicon, while manganese is entirely absent, which is somewhat remarkable, since nearly all iron contains some manganese. From microscopical examination and other tests it results that the specimens represent wrought iron rather than steel. They somewhat resemble puddled iron, and seem to have been made from rather impure ore. The percentage of carbon is low, as is the case for other impurities, with the exception of phosphorus. Slag is present in considerable quantity in a lumpy, irregular form, indicating that the material was not submitted to the amount of forging undergone by modern wrought iron.—Prof. J. S. **Townsend**: The conductivity of a gas between parallel plate electrodes when the current approaches the maximum value.—Hon. R. J. **Strutt** and A. **Fowler**: Spectroscopic investigations in connection with the active modification of nitrogen. II.—Spectra of elements and compounds excited by the nitrogen. The chief results are as follows:—(1) The spectra generated by the nitrogen afterglow do not differ fundamentally from those which can be produced by other means of excitation. In many cases, however, band spectra are better displayed, and the more refrangible parts of the spectrum are more completely developed. The method therefore adds to our resources for the production of spectra. (2) The spectra of metallic substances approximate to those obtained in the electric arc, or are intermediate between arc and flame spectra. (3) The band spectra given by iodine, chloride of tin, and mercuric iodide are very similar to those obtained from vacuum tubes. (4) The spectra exhibited by sulphur, sulphuretted hydrogen, and carbon disulphide consist of bands which are quite distinct from those given by sulphur in a vacuum, but resemble the bands of the carbon disulphide flame in air. (5) The cyanogen spectrum which is developed in the glow by cyanogen and certain other compounds of carbon differs in several respects from that observed in the cyanogen flame or carbon arc. Some of the differences appear to be due to the production of the spectrum at a relatively low pressure in the glow. A new set of bands, occupying positions near the most refrangible edges of the violet groups, occurs in the glow spectrum, and has also been observed during the phosphorescent combustion of cyanogen in ozone.—A. **Fowler** and H. **Shaw**: The less refrangible spectrum of cyanogen, and its occurrence in the carbon arc. (1) Revised wave-lengths are given for the bands forming the less refrangible part of the cyanogen spectrum. Numerous bands which have not previously been recorded are included. (2) The heads of the bands can be arranged in regular series similar to those constituting the first positive band spectrum of nitrogen. (3) There are considerable variations in the relative intensities of the various bands, according as the spectrum is obtained from the flame of the burning gas, from a vacuum tube, or from the luminous glow produced by the interaction of certain compounds of carbon with active nitrogen. (4) The complex spectrum of the carbon arc in the red and yellow is almost entirely due to cyanogen. (5) The spectrum of cyanogen in the sun is not of sufficient intensity to give visible indications of the red and yellow bands.—Sir W. **Ramsay**: Note on the monatomicity of neon, krypton, and xenon.—H. M. **Budgett**: The adherence of flat surfaces. This paper deals with the various causes producing adherence between plane surfaces which have simply been "wrung" together, and experiments are described which were carried out with specially prepared steel gauges. It is shown that the effects of atmospheric pressure and molecular attraction between the opposing faces are very slight, and that the adherence is chiefly due to the presence of a minute liquid film between the gauges. Tables are given comparing the force required to pull the gauges apart when various liquid films were present, and also comparing the readings obtained when separation occurred in air and in a vacuum. Photomicrographs are shown illustrating the distribution of a paraffin film over the steel, and proving that only a small area of the faces is covered by the liquid. The breaking strains of various liquids are estimated from microscopic measurement of the area of cross-section under strain, and it is shown that the tensile strength of water approaches ... atmospheres under these conditions.—G. D. **West**: The resistance to the motion of a thread of mercury in a glass tube. It is shown by theory and experiment that if a mercury index is to be moved along a glass tube of small bore with a velocity v, the difference of pressure P on the two ends of the index is given by

$$P = 0{\cdot}038/a + 8l\eta v/a^2,$$

when a is the radius of the tube and η the coefficient of viscosity of mercury.—A. J. **Berry**: The distillation of binary mixtures of metals in metals *in vacuo*. Part I.—Isolation of a compound of magnesium and zinc. Attempts have been made to isolate definite compounds of two metals, one of which, at least, is readily volatile, by distillation of the excess of the more volatile constituent; compare Heycock and Neville (Trans. Chem. Soc., 61, 1892, p. 914). In the present case it has been shown that the compound $MgZn_2$ discovered by Grube (*Zeitsch. anorg. Chem.*, 49, 1906, p. 77) can be prepared by heating a mixture of magnesium with an excess of zinc *in vacuo*. The excess of zinc distils off, and the residual alloy consists of the intermetallic compound. It has further been shown that this compound can be distilled without decomposition. —F. J. **Selby**: Analysis of tidal records for Brisbane for the year 1908. This paper gives the results of an analysis of one year's tidal records for Brisbane. The analysis was made by the method of Sir G. H. Darwin, the tidal abacus devised by him being employed. The results are generally in good agreement with those given by Rolin A. Harris for Sydney, as deduced from a year's observations of high and low waters. Using the constants given by the analysis, a curve was run off on the Indian tide-predicting machine at the National Physical Laboratory, and from a comparison of this with the actual records it was concluded that the values of the constants obtained were satisfactory.—Henry E. **Armstrong**, E. Frankland **Armstrong**, and E. **Horton**: Herbage studies. I.—*Lotus corniculatus*, a cyanophoric plant. Early in the summer last year plants of *Lotus corniculatus* growing on the Thames banks near Reading were found to contain a cyanophoric glucoside, but hydrogen cyanide could rarely be detected in plants from various localities collected later in the season. This year specimens have been obtained from a great variety of British localities, and these have rarely been tested without obtaining positive results. The climatic conditions during the two seasons have been very different, so that the differences observed between plants grown in the two years would seem to be mainly due to climatic differences. This year plants have also been obtained from all over Europe—from Norway, France, Holland, Germany, Russia, Servia, and Italy. In no case was cyanide found in plants growing in Norway, where the conditions have been such as to favour luxuriance rather than "maturity" of growth. The specimens obtained from other European localities in a majority of cases contained cyanide. The glucoside is usually accompanied by a corresponding enzyme, but this may occur without the glucoside. Wherever collected, the variety of *L. corniculatus* known as *major* (*uliginosus villosus*) has been found to be free from glucoside and enzyme; it would therefore seem that

otanists are justified in ranking this form as a distinct pecies.—B. **Hopkinson**: A high-speed fatigue tester and ie endurance of metals under alternating stresses of high equency. In this apparatus the test-piece (¼″ diameter y 4″ long) is fixed vertically, the lower end being attached heavy masses. The upper end of the piece carries a eight. The weight is attracted by an electromagnet laced above it and excited by alternating current. The ull thus applied varies periodically between zero and a aximum value, the frequency of the variation being vice that of the current. The test-piece behaves as a pring, the lower end of which is held fixed, while the pper end carries the weight and is free to move in a ertical direction. The adjustments are such that the atural period of vertical oscillations of this system is pproximately equal to the period of the varying magnetic ull, which accordingly sets up large forced oscillations of s own period. By thus using the principle of resonance ith a current frequency of 60 periods per second the nge of pull applied by the magnet may be magnified from to 70 times, and the stress produced in the piece can adily be made to alternate between 20 tons per square ch tension and 20 tons per square inch compression. he number of complete cycles per minute is 7200, and 000,000 reversals can be performed in 2½ hours. The st-piece is fitted with a simple form of optical extenso-eter whereby continuous observation can be kept of the ange of length occurring in a cycle of stress. From the ange of length the stress can be calculated if the piece approximately perfectly elastic under the stress which being applied. An independent estimate of the limits of ress can also be obtained by observing with a microscope e range of movement of the weight and calculating its cceleration from that range on the assumption (the justifi-ition of which is fully discussed in the paper) that the otion is simple harmonic. These two methods of getting e stress were found to agree closely for the mild steel sed in the experiments up to a range of stress of about tons per square inch. Endurance tests made in the ew machine on mild steel showed that the steel would and at least twenty million cycles of stress covering a nge of 29 tons per square inch. Comparative tests of e same steel made by Dr. Stanton at the National hysical Laboratory in a direct-stress testing machine ving about 1100 reversals per minute showed that at this eed the probable life of the material under the same nge of 29 tons per square inch would be less than o,000 reversals. Similar comparisons with both higher d lower ranges of stress confirmed the conclusion that at e high speed of more than 7000 reversals per minute the durance is much greater than at 1100 reversals per inute, both in the number of cycles and in the actual ne required to produce fracture.

Royal Meteorological Society, November 15.—Dr. H. N. ickson, president, in the chair.—C. **Harding**: The normal weather of the past summer. The author pre-nted statistics showing the distribution of temperature, infall, and sunshine week by week in the various districts the British Isles, and also made a comparison of the sults with the Greenwich Records back to 1841. From e facts thus brought together, Mr. Harding showed that far as temperature is concerned the summer of 1911 was ique. The maximum temperature of 100° at Greenwich August 9 is the highest temperature recorded in the ritish Isles since the establishment of comparable ob-rvations. The mean temperature for the summer was also gher than for any similar period during the last seventy ars. The maximum temperature of 96° in July has only en slightly exceeded on two previous occasions, and the ptember temperature of 94° has not previously been ualled during that month. So many hot days during the mmer have never before been recorded. Mr. Harding rther showed that the rainfall for the three summer onths has only been smaller in three previous years during e period of seventy years, and also that the duration of ight sunshine was greater than in any previous summer ice the introduction of sunshine recorders in 1881. As a nsequence of the exceptional weather the harvest was erywhere commenced at an earlier date than usual, and as quickly concluded under the most favourable conditions. The effects of the drought, other than in relation to the water supply and vegetation, were very far reaching. —W. **Larden**: Observations of solar halos.

Zoological Society, November 21.—Dr. S. F. Harmer, F.R.S., vice-president, in the chair.—Dr. Geoffrey **Smith**: The fresh-water crayfishes of Australia. The object of this paper was to revise the classification and nomenclature of the Australian and Tasmanian crayfishes, and to give diagnoses of the genera and species with their limits of distribution. The work was based on a large material obtained from all parts of the continent and from Tasmania. Many of the specimens had been collected by the author, but the majority formed a very large collection brought together during the past twenty years by Prof. Baldwin Spencer. Four genera were recognised, Astacopsis, Chærops, Parachærops, and Engæus; the first three genera included the fresh-water crayfishes proper, and the last-named genus contained the land crayfishes, which were not dealt with in this paper. The geographical distribution of these genera and its bearing upon the geographical problems of Australia was discussed, and the view was supported that the Bassian subregion represented the home of the Australian crayfish, and that Astacopsis was nearest the ancestral form.—F. E. **Beddard**: A new genus of tapeworms from the bustard (*Eupodotis kori*). Four complete specimens and some fragments of this cestode had been obtained from a South African bustard in the society's gardens, and the author regarded it as a member of the group Tetracotylea, but could not reconcile its characters with those of any other genus of that group at present known. He briefly described its anatomical characters and discussed its systematic position, and proposed a new genus and species for its reception.—A. E. **Cameron**: The structure of the alimentary canal of the stick-insect, *Bacillus rossii*, Fabr., with a note on the parthenogenesis of this species. The author stated that this insect had a rather limited distribution, occurring in the south of Europe and in the north of Africa, and that in the wild state it was not found north of Orleans. Certain peculiarities of the alimentary canal were dealt with which were regarded as adaptations to the mode of life of the species. Attention was directed to the fact that the male was only rarely found in the wild state, and that parthenogenetic reproduction of *B. rossii* had been verified, for during four generations the specimens kept by the author had showed no males. The fact that the males were disappearing suggested that parthenogenesis was not the primitive method of reproduction, but that the species had become adapted to it through the failure of sexual reproduction.—H. B. **Preston**: A collection of terrestrial and fluviatile shells made by Mr. Robin Kemp in British and German East Africa. One new genus and thirty-four new species were described, which represented only a very small portion of the large number of species collected.—G. A. **Boulenger**: The habits of British frogs and toads. The paper gave information for those who might feel inclined to carry out further observations on the subject of the migrations of Amphibia as dealt with in a paper recently read before the society. The common toad was strongly recommended as the most suitable batrachian on which to institute series of experiments on distant orientation.—R. **Lydekker**: Milk-dentition of the ratel. The author described an instance of primitive features present in the milk-dentition being entirely lost in the teeth of the permanent series. So far as he was aware, no such atavistic feature had been hitherto recorded in the case of any existing mammals.

Geological Society, November 22.—Prof. W. W. Watts, F.R.S., president, in the chair.—Prof. T. G. **Bonney**, F.R.S., and Rev. E. **Hill**: Petrological notes on Guernsey, Herm, Sark, and Alderney. Further study has been given to the relations of the igneous masses. The old distinction between diorite and syenite cannot be maintained; there exists, especially in Guernsey and Alderney, a dioritic magma, which underwent differentiation. The results of this are described, the most basic being found at Fort Albert (Alderney) and Bon Repos Bay (Guernsey), and the most acid, which are really tonalites, in the north-west of the latter island. These and a felspathic variety

sometimes intrude, sometimes pass into the others, so they also must have been at high temperature. The so-called "granites" at the two ends of Sark are hornblendic, the southern one being really a tonalite; so are those of Alderney, Herm, Jethou, and Guernsey, and it is suggested that these granites may be yet more acid terms in a differentiation series. Of the numerous dykes, the most acid are either aplitic micrograpites or quartz-felsites. Diabase-dykes are common, and mica-traps have been found in all the islands except Herm. At Pleinmont, in the south-west of Guernsey, a mass resembling a greenstone proves to be sedimentary. The time-relations of the several rocks are discussed. The gneiss of Guernsey is the oldest, and had acquired its structure before the intrusion of the diorites. They were followed by the hornblendic granites, and these by the aplitic micrograpites. All were pre-Cambrian. The date of the diabase-dykes is more uncertain. The mica-traps are probably late Palæozoic.—H. **Woods**: The evolution of Inoceramus in the Cretaceous period. The species of Inoceramus found in the Gault, the Upper Greensand, and the Chalk are considered to have descended from two stocks which occur in the Lower Greensand, one being *I. salomoni*, d'Orb., the other of the type of *I. neocomiensis*, d'Orb. (1) *I. concentricus*, Park. (Lower and Upper Gault), is of the same type as *I. salomoni* (Folkestone beds and Mammillatum bed), from which it has been derived. *I. sulcatus*, Park. (Upper Gault), closely resembles *I. concentricus*, except that it possesses strong radial ribs. Between these two species every gradation is seen. *I. tenuis*, Mant. (Red Chalk and Chalk Marl), is allied to *I. concentricus*, from which it has been derived by an increase in the length of the hinge and a decrease in the prominence of the left umbo. (2) *I. anglicus*, Woods (Gault and Upper Greensand), resembles *I. neocomiensis*, but the posterior part of the shell has become more compressed, and the ventral curvature of the ribs has increased. From *I. anglicus* two species appear to have arisen, namely, *I. pictus* and *I. crippsi*. (*a*) *I. pictus*, Sow. (Chalk Marl to *H. subglobosus* zone), approaches the form of *I. anglicus*, which has more numerous and more regular ribs; and in it the ribs have become still more numerous and more regular, and the anterior area has become more extensively developed. (*b*) *I. crippsi*, Mant. (Upper Greensand to zone of *H. subglobosus*), agrees in many respects with the form of *I. anglicus*, which has fewer and less regular ribs; but in this species the hinge has become somewhat shorter, the postero-dorsal part of the shell less compressed, the anterior area smaller, the ribs fewer and more irregular, with a less strongly marked posterior curvature.

CAMBRIDGE.

Philosophical Society, November 13—Sir George Darwin, K.C.B., F.R.S., president, in the chair.—Sir J. J. **Thomson**: Application of positive rays to the study of chemical reactions. The author describes the results of the application to chemical reactions of a method which he brought before the notice of the society at a previous meeting. The production of carbon monosulphide when an electric discharge passes through the vapour of carbon bisulphide was detected by this means. The author gives the results of investigations on the chemical combination between hydrogen and oxygen and hydrogen and nitrogen, and discusses the source of curves corresponding to atomic weights 1–6, 2–5, 20–21, 39, 50–51, which do not fit in with recognised elements or compounds.—N. **Bohr**: Electron theory of metals. In the paper an attempt is given to generalise the theory of H. A. Lorentz, retaining, however, the main assumptions used by this author. It is shown that, by making alterations in the special assumptions used by Lorentz, results can be obtained for the electric and thermal conductivities and for the galvano-magnetic phenomena, which agree more closely with the experiments. On the other hand it is shown that the calculation of the absorption and emission of heat rays with long times of vibration in all the considered cases leads to the same law of heat radiation as given by Lorentz, and that, further, the remarkable conformity between Lorentz's calculation of the thermoelectric phenomena and the thermodynamic theory of these phenomena given by Lord Kelvin will remain unchanged in all the considered cases. Finally, it is shown that the presence of free electrons, contrary to the generally adopted opinion, will not give rise to any magnetic properties of the metals.—J. C. **Chapman**: Secondary characteristic Röntgen radiation from elements of high atomic weight. The secondary Röntgen radiation has been examined from lead which belongs to the more or less unknown second group (group L, Barkla, *Phil. Mag.*, September) as regards its characteristic radiation. It was found that lead shows a marked homogeneous constituent mixed with the scattered radiation. λ/ρ in Al=16·8 ($I = I_0 e^{-\lambda x}$, ρ=density of Al). The absorption by the element lead in the form of lead oxide was measured for a series of homogeneous beams of group K, and it was shown that lead exhibits a marked selective absorption in the region where it commences to be excited; thus between selenium, $\lambda/\rho=18·5$, and bromine, $\lambda/\rho=16·3$, the ratio of the absorption by lead to that by aluminium commences to rise, and continues to do so until the absorption band is passed. This would suggest that the mechanism of production and the resulting radiation in both groups is of the same type.

EDINBURGH.

Royal Society, November 13.—Prof. J. C. Ewart, F.R.S., in the chair.—Angus B. **Fulton**: Experiments to show how failure under stress occurs, its cause, and comparative values of the maximum stresses induced when timber is fractured in various ways. The objects of the research were to study the effects of the medullary rays on the strength of timber when strained in various ways, and to connect up the maximum induced stresses in cross bending with those obtained in tension and compression. Some of the conclusions arrived at were that the initial cause of fracture lies in the medullary rays; that rectangular beams when laid on a tangential face are stiffer and have a higher fracture value than when laid on a radial face; that rectangular beams of unequal sides are stiffer, but not materially stronger, when laid on the broad side of the section; that fracture by shearing does not take place in timber beams of the commoner woods, supported on the two ends and loaded in the middle, where the ratio of span to depth of beam exceeds seven.—Dr. G. Rutherford **Jeffrey**: A new method of measuring mental processes in normal and insane people, with special reference to maniac depressive insanity. The object of the research was to ascertain whether or not any definite characteristics of the mental working process could be detected in the disease, or group of diseases, described as maniac depressive insanity. The reckoning test, recently described by Maloney, was used. The test consisted of the addition of digits in pairs, each pair being taken to represent a constant unit of mental work. Not only was the number of units of mental work done throughout a given period ascertained, but also the number of units per minute throughout the same period. The number per minute of these mental units was then plotted against the time, and a curve obtained showing objectively the mental working capacity throughout the period. The experiment consisted in allowing thirty cases of maniac depressive insanity to perform the reckoning test for fifteen minutes on each of five successive days. Seven normal people were tested under the same conditions and for the same length of time. An average normal mental curve was obtained in this way, and this was compared with the curves obtained from the insanity cases already mentioned. The normal curve did not support Hylans's assertion that the middle period of five minutes represented best the maximum working capacity. As compared with the normal curve, the work curve of the maniac depressive cases differed markedly in two ways:—(1) a tendency toward a high output characterised the third five-minute interval, which the author regarded as being probably due to the difficulty which such patients experience in getting under weigh in the mental task, and as being an expression of their exaggerated psycho-motor inertia; (2) the small extent of the terminal spurt, possibly due to the fact that the imminence of the end of the task, which acts as an incentive to greater effort in normal people, is not realised. The curves varied in form according as the patients were in the quiescent, depressed, or excited phases of the disease. For example, in the depressed patient's chart, the

recovery was performed in a series of steps, while in the excited cases the curve demonstrated incessant and abrupt transitions of mental energy in a morbidly excited brain. The author agreed with Maloney that the reckoning test was of distinct therapeutic, and possibly also diagnostic, value in psychiatry.—Prof. Alex. **Smith** and C. M. **Carson**: The freezing points of rhombic sulphur and of *soufre nacré*. When pure liquid sulphur freezes into the monosymmetric, the rhombic, or the *soufre nacré*, the freezing points are respectively 119·25°, 112·8°, and 106·8° C. When the liquid sulphur contains the insoluble sulphur in equilibrium, the freezing points become respectively 114·5°, 110·2°, and 103·4° C.

Paris.

Academy of Sciences, November 27.—M. Armand Gautier in the chair.—The president read a letter from Prince Roland Bonaparte putting at the disposition of the academy a sum of 250,000 francs to be used for facilitating research by young scientific men. It is not to be given in the form of a reward for work already done. The intention is that the amount should be given in five annuities to men who have already given proof of their capacity for original work, and, not being members of the academy, lack sufficient resources to pursue their investigations.—A. **Chauveau**: A phantom image of the Eiffel Tower observed in 1900. A detailed description of the phenomenon observed is given, together with an explanation as to its probable cause. It would appear to be analogous with the shadows known as the spectres of the Brocken.—M. Leclainche was elected a correspondant for the section of rural economy in the place of M. Eugène Tisserand, elected free academician.—F. A. **Forel**: The Fata-morgana. A discussion of the conditions under which this phenomenon appears on Lake Leman.—E. **Barré**: The minimum surfaces produced by a circular helix.—Emile **Cotton**: The instability of equilibrium.—M. **Jouguet**: The velocity and acceleration of waves of shock of the second and third species in wires.—André **Léauté**: Certain difficulties presented by the use of exponential developments.—J. **Danysz**: The β rays of the radium family. It has been shown in a previous communication that a glass tube containing radium emanation gives off at least seven bundles of β rays with different and determinate velocities. Fresh experiments on these rays have been carried out with a view to determine their velocities with the highest possible precision. Twenty-three bundles were distinguished, seven of which are strongly marked on the plate. The emanation from 0·3 gram of radium chloride was utilised for these experiments; the strength of the magnetic fields used varied from 600 to 6000 gauss.—Félix **Leprince-Ringuet**: The geometrical properties of the point representing the earth in the diagram of the voltages of a polyphase network.—G. Ter **Gazarian**: A general relation between the physical properties of bodies: application to viscosity, capillarity, surface energy, heat of vaporisation, and the rectilinear diameter. If q_1 and q_n are the quotients of the numbers representing the densities of bodies compared at temperatures t_1 and t_n, equally removed from the critical points, then the relation $q_n = q_1 + c(t_n - t_1)$ has been proved in a previous paper. The same equation has now been extended to other physical properties, the calculated and observed values of q showing a good agreement.—Albert **Colson**: The dissolecule and the formula of van 't Hoff. A reply to the criticisms of Girard and Henri. The author objects to the identification of osmotic pressure in solution with the pressure of gaseous molecules.—René **Dubrisay**: Chemical equilibria in solution. A study of the effect of the addition of acetone on the hydrolytic dissociation of bismuth nitrate.—L. C. **Maillard**: The condensation of the acid amines in presence of glycerol; cycloglycylglycines and polypeptides. A mixture of glycocoll with four or five times its weight of glycerol heated in a sealed tube to 170° C. gives a good yield of cycloglycylglycine.—J. A. **Le Bel**: The dimorphism of rubidium bichromate.—A. **Goris** and M. **Mascré**: The chemical composition of some of the higher fungi. Urea is present in some species and absent in others. Two cholesterols were also extracted, and a new substance, as yet not identified.—Paul **Macquaire**: Tyrosine as a fixing agent in the preparation of the iodopeptones.—H. **Labbé** and L. **Violle**: The ingestion of mineral acids in a dog from which the pancreas had been partially removed.—J. **Courmont** and A. **Rochaix**: The duration of immunisation, by the intestine, against experimental Eberthian infection in the rabbit. The immunity was found to be appreciable at the end of six months.—André **Lancien**: Electric colloidal rhodium. Starting with carefully purified rhodium, colloidal rhodium has been obtained by a modification of Bredig's method. The diameter of the particles of colloidal metal was about 5 $\mu\mu$. The colloidal rhodium solution was found to be without toxic properties when injected into fish, frogs, rabbits, and dogs, although the solution prevented the development of certain micro-organisms. Details are given of the application of this solution in therapeutics with beneficial results.—Etienne **Rabaud**: The cause of the isolation of solitary larvæ.—Edgard **Hérouard**: Parthenogenesic progenesis in Chrysaora.—M. **Rappin**: Antituberculous vaccination and serotherapy. Tubercle bacilli, after their virulence has been modified by a chemical treatment, are injected into the horse, from which a serum is prepared possessing a high agglutinating power. Experiments with this serum are described.—F. **Mesnil** and J. **Ringenbach**: The action of serums from the Primates on the human trypanosome of Rhodesia.—Carl **Renz**: The extension of the Trias in the middle portion of eastern Greece.—H. **Douxami**: The seismographic observation at Lille of the earthquake of November 16, 1911. The true displacement of the ground at Lille varied between 0·2 and 0·3 millimetre.

New South Wales.

Linnean Society, October 25.—Mr. W. W. Froggatt, president, in the chair.—R. **Greig-Smith**: Contributions to a knowledge of soil-fertility. No. iii., Bacterial slimes in soil. Many of the bacterial colonies that develop on saccharine media, after sowing with dilute suspensions of soil, contain gum or slime. As the bacteria actively produce the slime upon isolation, it is reasonable to suppose that their slime-forming faculty was being exercised while they were in the soil. Bacterial slimes, therefore, should be detectable in soils, if the conditions had been such as to prevent their decomposition. The investigation of a rich soil showed that slime was present; and, as it contained galactans which are typical of bacterial slimes, it probably had a bacterial origin.—A. H. S. **Lucas**: The gases present in the floats (vesicles) of certain marine algæ. The author, not having been able to find any account of actual analyses of the gases present in the floats of marine algæ, made a number of analyses of the gases found in the floats of *Phyllospora comosa, Hormosira banksii,* and *Cystophora monilifera*. In all cases, the gases consisted of oxygen and nitrogen only; in most cases the proportion of the oxygen was less than if air had been taken directly into the floats, and in all notably less than in air dissolved in water. In the floats of growing Hormosira, the proportion of oxygen was about 12 per cent. only of the total volume of contained gases. While there is no absolute evidence of the source of the gases, the author inclined to the view that they are derived from the air dissolved in the sea-water, the plant using up a considerable proportion of oxygen for its process of metabolism.—D. **McAlpine**: The fibrovascular system of the apple [Pome], and its functions. In a transverse section of the stalk of an apple, just as it enters the fruit, there are normally ten vascular bundles—or twelve if six carpels are present; eight if four—though sometimes two adjoining bundles may become confluent. These, on entering the fruit, spread out to form ten main trunks with numerous branches, and conveniently situated midway between the skin and the centre. The earliest branching and the most direct course is towards the carpels and the seed; then the flesh is supplied by numerous diverging branches, which unite to form a network of vessels, and finally terminate, beneath the skin, in a perfect maze of the most delicate forked veinlets. By macerating an apple in a weak solution of potassium hydrate for a week, and then removing the soft parts in water, with the aid of a brush and a needle, the fibro-vascular system may be isolated in a more or less intact condition. This system must not be conceived of as a vast network of tubes conveying food-material to a definite terminus, but as being tapped on the way by living tissue wherever growth is going on, or storage is required.

CONTENTS.

THURSDAY, DECEMBER 14, 1911.

GÖTTERDÄMMERUNG.

The Golden Bough: a Study in Magic and Religion. By Prof. J. G. Frazer. Third edition. Part iii., "The Dying God." Pp. xii+305. (London: Macmillan and Co., Ltd., 1911.) Price 10*s*. net.

THE third part of "The Golden Bough" is an expansion of a portion of the third chapter of the second edition. Its title, "The Dying God," indicates the chief concern of the whole work, for it might well apply to four of the six parts. To the other three, "Adonis, Attis, Osiris," "The Man of Sorrows," and "Balder the Beautiful," it is related as genus to species.

Prof. Frazer is to be congratulated on having discovered the missing link, which he has long desiderated, in the chain of evidence required for his explanation of the fantastic rule of the priesthood of Nemi, which forms the text of his encyclopædic work. This discovery is one of the two chief portions of new matter introduced. Dr. C. G. Seligmann has discovered among the Shilluk of the White Nile a "coronation ceremony" which, in Prof. Frazer's cautious phrase,

"appears to be intended to convey to the new monarch the divine spirit of Nyakang, which has been transmitted from the founder of the dynasty to all his successors on the throne."

The practice of killing divine kings had been previously made out by the author, but the fact of succession to the soul of the slain monarch, though strongly suggested by many analogies, was still lacking. The Shilluk apparently supplied the omission.

The point calls for something more than mere mention, since it is of vital importance not only for the explanation of the Nemi priesthood, but for the general principles of the whole practice of superstitious regicide. A few extracts from Prof. Frazer's account will serve to make the point clear.

"The reverence which the Shilluk pay to their king appears to arise chiefly from the conviction that he is a reincarnation of the spirit of Nyakang, the semi-divine hero who founded the dynasty and settled the tribe in their present territory."

The religion of the Shilluk consists mainly of the worship paid to Nyakang. One of his most famous shrines is at Fashoda. Every shrine is called a grave of Nyakang, "though it is well known that nobody is buried there." Nyakang is the rain-giver of the country. Being incarnate in the reigning king, it is believed with "conviction" that the latter

"must not be allowed to become ill or senile, lest with his diminishing vigour the cattle should sicken and fail to bear their increase, the crops should rot in the fields, and man, stricken with disease, should die in ever-increasing numbers."

To prevent all this "it used to be the regular custom with the Shilluk to put the king to death whenever he showed signs of ill-health or failing strength." The old custom is said to have been the walling-up of the king in a specially built hut, where he died of hunger and suffocation. This custom "was abolished some five generations ago," and the Shilluk have adopted

"a quicker and more merciful mode. . . . What the exact form of execution has been in later times Dr. Seligmann found it very difficult to ascertain, though with regard to the fact of the execution he tells us that there is not the least doubt. It is said that the chiefs announce his fate to the king, and that afterwards he is strangled in a hut which has been specially built for the occasion."

Moreover, even while enjoying health and strength, the king might be attacked at any time by a rival.

"According to the common Shilluk tradition any son of a king had the right thus to fight the king in possession, and, if he succeeded in killing him, to reign in his stead."

In a note Dr. Seligmann is quoted as saying:—

"The assumption of the throne as the result of victory in single combat doubtless occurred once; at the present day and perhaps for the whole of the historic period it has been superseded by the ceremonial killing of the king, but I regard these stories as folk-lore indicating what once really happened."

At the investiture of the new king, a mysterious object called Nyakang is used. It

"is said to be of cylindrical shape. . . . The chief of Akurwa informed Dr. Seligmann that the object in question is a rude wooden figure of a man. . . . We may suppose that it represents the divine king himself, and that it is, or was formerly, supposed to house his spirit, though the chief of Akurwa denied to Dr. Seligmann that it does so now."

The object is placed on the royal stool, a leg of which is held by the king.

There is a lack of absolute certainty about the whole account. Dr. Seligmann has not seen the "Nyakang" nor a coronation. As for the residence of "the holy spirit of Nyakang" in the object bearing his name, all we have is the remark, "as Dr. Seligmann with great probability conjectures."

This method of crystallising dogmas out of the fluid ideas of barbarous thought is very characteristic of the inductive processes of the author. It may be said to constitute both his weakness and his strength. The rationalist may observe that the actuality of the Shilluk customs is mechanical common sense guided by the principle that might is right. The king must be a strong man both for his own and his people's sake. When a stronger man comes, he is liable to the incidence of this principle. When he himself decays, he is "relieved" of his duties, in the most effective way. Everything else is superstitious accretion, *ex post facto*, and of no practical importance. But when, as may happen in organised religions, such accretions crystallise into form, and are used as social or political levers upon the popular will, their importance may be far-reaching. Probably no one is better aware of this distinction than the author, but he has his own characteristic method of painting the social dangers of unscientific beliefs.

The other new subject in the volume has a similar aspect. This, put baldly, is the suggestion that the victors in the great Greek games were originally

"divine kings" and "dying gods." Victory in the race meant reigning for a term of years as an embodiment of the sun. Defeat at the end, a mark of senile decay, meant the death of the old, and the ascension of the new, god-man.

One may doubt whether early thought so welded together in actual practice the notions of god, king, priest, and man; but the ideas were a mixture, if not a compound.

The new matter thus, by emphasising the form of the inquiry, considerably increases its value, if we accept its form. This is the artistic side of the book, such as every scientific theory must possess.

The new edition of "The Golden Bough" is addressed to a new generation which has succeeded to the soul of a former generation impregnated with the teaching of the earlier editions. Its influence is certain to be proportionally cumulative and far-reaching.

A. E. CRAWLEY.

THE SCOURGE OF TROPICAL AFRICA.

A Handbook of the Tsetse-flies [*Genus Glossina*]. By E. E. Austen. Pp. x+110+x plates. (London: Printed by order of the Trustees of the British Museum. Sold by Longmans and Co., B. Quaritch, Dulau and Co., Ltd., and at the British Museum (Natural History), 1911.) Price 5*s.* 6*d.*

THE increasing attention which has been paid during the last few years to the collection and observation of tsetse-flies (Glossina) has led to the discovery of so many new species that the exhaustive monograph of this genus, published by Mr. E. E. Austen eight years ago, is now much out of date. The concise revision of the species by the same author now issued by the Trustees of the British Museum will therefore be most welcome to all who are concerned with the study of these formidable pests. In the original monograph only seven species were described, whereas now no fewer than fifteen are enumerated (excluding *Glossina maculata*, Newst., and *G. submorsitans*, Newst., to which the author does not accord specific rank), and two of these are described for the first time.

As a result of his examination of the male genital armature of all the known species, except *G. maculata*, Newst., and *G. fuscipleuris*, Aust., Prof. R. Newstead has shown that these structures present three markedly different types, which appear to afford a useful indication as to the mutual interrelationships of the species, especially as they coincide with the more important external distinctions. These sections he called respectively the *palpalis*-group, the *morsitans*-group, and the *fusca*-group. Mr. Austen has departed from this arrangement by dividing the last-named group into two, the only constant character given for separating these divisions being a difference in the tint of the wings. Wing-colour, however, has clearly no value as a group-character in this genus, and the proposed subdivision is open to the serious objection that it obscures the existence of important structural affinities, without any compensating advantage.

Apart from this, the synoptic tables for the determination of the groups and the species leave little to be desired. The preparation of a really accurate and workable key for a genus which presents but few salient and stable specific characters is by no means so simple a matter as it may appear, but with these tables any intelligent field worker should be able to determine his species without much difficulty.

Each species is fully dealt with under the following headings:—description, distribution, bionomics, and affinities and distinctive characters. The information given with regard to habits and life-histories indicates how very little we yet know of the bionomics of these insects, except in the case of two or three species. The puparia of six different species are now known, and these have all been figured (pp. 5 and 7). It is interesting to note that these structures exhibit distinctive specific characters, so that the discovery of even empty puparia may serve to throw some light upon the breeding habits of the various species.

From the point of view of a field worker this excellent handbook has only one drawback, namely, that no information whatever is given concerning the bionomics of the most important species, *G. palpalis*, the carrier of sleeping sickness; the reason adduced being lack of space. In these circumstances much of the unduly elaborate and highly technical description of the generic characters might well have been eliminated, while several pages have been wasted by the needless repetition of the synoptic tables.

The genus Glossina appears to attain its maximum development in the humid region of equatorial West Africa. From Southern Nigeria no fewer than nine different species have already been recorded, the Gold Coast coming next with eight. From Northern Nigeria five species are known, the remaining British colonies each having only four or less.

We may reasonably assume that all these insects are potentially capable of conveying serious diseases to men or domesticated animals, yet it must be admitted that so far no method has been devised for compassing their destruction in an effective manner. It is true that in certain places the clearing of forests has caused tsetses to withdraw, but this is a measure which is capable of only limited application, and might even defeat its object if done on too large a scale. As a rule, insect pests are most easily destroyed during the larval stage, but such a course is rendered impossible in the case of Glossina owing to the fact that the larva completes its development in the body of the mother. Thus we have to undertake the much more difficult task of destroying the perfect insect; and it is to be regretted that no serious attempts appear to have been made in the British colonies to test the method of trapping the flies with bird-lime, which has been attended with considerable success in the Portuguese island of Principe.

The remedial measure most generally suggested is to cut off the food supply of the insects by killing all the larger mammals. But advocates of this course are apt to forget that unless the flies are absolutely dependent for their existence upon these large mammals only, the remedy cannot be really effective. The writer has had occasion recently to examine a number of reports bearing upon this question, and the statements made are often highly conflicting; but still,

there appears to be some trustworthy evidence that tsetse-flies, including even *G. morsitans*, can exist in numbers where big game is negligible as a food supply.

These wider questions are beyond the scope of Mr. Austen's handbook, which, however, contains a store of information which will be invaluable to those who are seeking to free Africa from the tyranny of these dangerous pests. G. A. K. M.

THE PSYCHOLOGIST AND THE TEACHER.

The Psychology of Education. By Prof. J. Welton. Pp. xxi+507. (London: Macmillan and Co., Ltd., 1911.) Price 7*s.* 6*d.* net.

WHATEVER criticism Prof. Welton's book may excite, it is undeniably interesting—the most interesting book dealing with its particular problems that has been produced in recent years. With great ability and clearness, the author has drawn a map of life, not as the adult lives it, but as it develops in form and complexity from infancy to manhood. The teacher and the situations with which he deals are in his mind all through. His book is therefore not a treatise on psychology, yet the psychologist's point of view is so dominant that neither does it set forth a theory of education. This Prof. Welton makes clear in his preface. His concern is with the connections between the two—psychology and education—and especially to give a psychological explanation of educational procedure.

The book will surely make a very strong appeal to experienced teachers, for its style is attractive and conspicuously free from abstruse technicalities of expression. Indeed, one is tempted to think that the author has been over-anxious to conciliate the teacher. His opening chapter is particularly addressed to the practical man, who will not fail to note that the psychology which "alone is of worth to the educator" is that "which comes from constant and sympathetic intercourse with children." Although careful reading makes it clear that Prof. Welton means less than he seems to say, it is a mistake, we think, even to seem to imply that all good teachers are willy-nilly good psychologists. There is a distinction between psychological knowledge and a practical acquaintance with psychical relations which comes from experience. The child who uses a brick differently from a ball is not a physicist, nor does social tact constitute a claim to knowledge of psychology. "Every true educator is always making use of real psychology." Is then every true farmer always making use of real chemistry?

The restrictions which the author laid upon himself have led to some difficulties. He very rightly protests against the implicit view of so many child psychologists that children are different from men by reason of their incompleteness.

"Progress is not from a mutilated and incomplete mind to one which possesses all its organs. At every stage of his development, a child's experience is as full and satisfying to him as is that of a philosophical psychologist to himself."

Instead of the serial appearance of new powers to determine the order of which is the main task of the genetic psychologist, his aim should be to show how such development is brought about. All this is admirably put, and as admirably describes the author's object.

In his effort to avoid technical language, however, Prof. Welton has not always been able to achieve satisfying analyses of the processes he describes. In his discussion of the nature of imitation, he restricts the use of the word to what most psychologists call deliberate imitation. This is, of course, giving the word a technical sense, for we call monkeys imitative, though we may deny their intention to imitate. It is no doubt to the writings of M. Tarde that Prof. Welton's protest is due. M. Tarde would find an element of imitation in all that we do, and a term which includes so much tends to obscure rather than to clarify thought. Our author has a second objection to the current use of the word in psychology. To call an action imitative when there is no intention to imitate is to describe its external rather than its psychical attributes. There is a certain justification for this criticism, but it is doubtful whether Prof. Welton's way out of the difficulty helps very much. He would avoid confusion by including all the non-volitional forms of imitation under the term assimilation—the general tendency of man to assimilate his mental life to that of his fellows. But how does such a term suit a case like that of Preyer's tiny infant who pursed his lips as he watched his father doing so? Surely this is distinguishable in analysis from catching the enthusiasm of a crowd.

These all-embracing words—assimilation, apperception, &c.—are a great difficulty in teaching psychology, and for that reason a precise technical terminology cannot be dispensed with. It is as necessary in this subject as in botany, if it is to justify its claim to rank as a science. The whole chapter on the nature of experience is the least convincing in a book which is otherwise extremely readable, and sane to the point of conservatism. No teacher can fail to find much that is helpful in its pages, though he must not expect to get from it an introduction to the methods and results of recent pedagogical inquiry. This Prof. Welton has deliberately left out, except for a gentle gibe at those who use chronoscopes, ergographs, and other terrible machines.

The book is admirably printed, and altogether a valuable addition to English educational literature.

J. A. Green.

TIMBER AND PAPER.

Wood Pulp and its Uses. By C. F. Cross, E. J. Bevan, and R. W. Sindall. With the collaboration of W. N. Bacon. Pp. xi+270. (London: Constable and Co., Ltd., 1911.) Price 6*s.* net.

"THE present is a Cellulose Age," remark the authors of the book before us. Their statement is not made *ad captandum*: it will, they urge, survive critical examination.

Perhaps in their epigram there is just a tinge of the spirit which makes every mother's goose a swan; but be that as it may, there is no doubt that cellulose plays a very important part in modern life. In the

clothing of men's bodies, as in the nurture of their minds, the difference between our own times and those of, say, the Stone age is obviously enormous; and—though this may be less obvious—the difference largely depends upon cellulose. For, not to mention high explosives and celluloid articles, if paper and papyrus, if cotton, flax, and similar textile materials are taken from us, we are back in the days of potsherd writing-tablets, woad, and fig-leaves—back, in fact, to an early stage of civilisation.

Typically cellulose is the purified fibre substance of cotton. Wood-pulp is a special combination of cellulose. In the fibres of wood, the cellulose is associated with substances which have the essential chemical characters of the di-ketones, and hence are designated "lignones." These are chemically much more reactive than the cellulose. Lignones, for example, are very susceptible to oxidation, even by the oxygen of the air, in this respect differing notably from cellulose. Hence paper such as modern "news" paper, which contains ligno-celluloses from wood-pulp as a constituent, on exposure to air and light becomes readily discoloured, and loses its tenacity. The ligno-celluloses are the essential fibrous components of "mechanical" pulp, which is merely wood disintegrated into its constituent fibres by grinding. On the other hand, since lignone is attacked by chlorine, by alkalis, and by alkali bisulphites, it can be separated with these reagents more or less readily from the cellulose with which it is associated, leaving the latter substance in a tolerably pure condition. This product is "chemical" wood-pulp ("soda" or "sulphite" pulp); it differs materially from, and is superior to, the fibre obtained by the mechanical process. Common "news" paper contains about 80 to 90 per cent. of mechanical wood-fibre, and 10 to 20 per cent. of wood-fibre which has been treated chemically; in high-class "news" paper these proportions are reversed. Naturally, "mechanical" wood-pulp is excluded from paper intended for permanent documents. It serves a useful purpose, however, in enabling the demand for cheap publications to be met.

Since cellulose in a more or less pure form can be separated from wood as "chemical" wood-pulp, the question naturally arises whether such pulp cannot be used as a source of cellulose for the production of textile fabrics, high explosives, and celluloid articles. Its relatively low price would seem to give it a considerable advantage. In fact, some success has been met with in respect of the first-named group; for example, in the manufacture of wood-pulp yarn ("silvalin") and of artificial silk (from "viscose"). But the shortness of the fibres is a serious limitation to the use of wood-celluloses for textile purposes. As regards the other groups, wood-cellulose when nitrated has been found to be less stable than cotton-cellulose nitrated to the same degree, and is therefore less suitable for these industrial uses.

The chief woods employed for the manufacture of "sulphite" and "mechanical" pulps are spruce, fir, and pine. For the production of "soda" pulp, aspen, conifers, poplar, and other deciduous trees are utilised; whilst hemlock wood is much used in the making of wrappers and "fibre" papers. After two introductory chapters, the authors discuss the sources of supply of such woods, and then proceed to describe the various operations involved in the manufacture of the several kinds of pulp. The rest of the book deals chiefly with the conversion of the pulp into paper and cardboard, and with its relation to the textile industries.

Professedly the work is written for the general reader, but there is much in it that would be appreciated by the young chemist beginning to specialise in cellulose products. Occasionally the style is heavy and not too clear; but the volume as a whole gives a good general idea of the wood-pulp industry, and the authors' names are a guarantee of its trustworthiness.

C. SIMMONDS.

DR LUNGE AND THE LEBLANC PROCESS OF ALKALI MANUFACTURE.

The Manufacture of Sulphuric Acid and Alkali with the Collateral Branches: a Theoretical and Practical Treatise. By Prof. G. Lunge. Third edition. Vol. iii., Ammonia-Soda, Various Processes of Alkali-making, and the Chlorine Industry. Pp. xix+764. (London: Gurney and Jackson, 1911.) Price 30s. net.

THESE handsome volumes, which we owe to the tireless industry of the emeritus professor of technical chemistry in the Federal Polytechnicum of Zürich, bring the history of the development of alkali manufacture and of its associated industries down to its latest phase. During the dozen or more years which have elapsed since the appearance of the last edition of Dr. Lunge's monumental work, considerable changes have occurred in this department of chemical technology which bid fair, in the fulness of time, completely to revolutionise its methods. A significant feature of modern manufacturing industry is the ever-growing application of electrical energy to its processes, and in no field of production has this application been more fruitful in consequences than in that of industrial chemistry. Although there is, even now, scarcely a single section of applied chemistry which has not felt the influence, directly or indirectly, of this form of energy, it is almost a truism to assert that we are only at the threshold of the new departure.

Dr. Lunge's books bring the story as far as the parting of the ways. He is the faithful chronicler of contemporary achievements, the historian *temporis acti*. He is concerned mainly in giving as full and as accurate a picture of the state of alkali manufacture at the end of the first decade of the twentieth century as is possible to him. As a faithful reflex of the present state of this manufacture the volumes before us suffer from the limitation that they deal only with what have grown to be subordinate processes—that is, processes which are dependent upon the conversion of common salt into alkali through the instrumentality of oil of vitriol, or, in other words, the Leblanc method of manufacture and its associated industries. The supremacy of this method has long since passed away by reason of the elaboration and development of the ammonia-

soda process of Dyar and Hemming. The Leblanc process lives mainly on account of the commercial value of its by-products, but its continued existence even from this cause is seriously threatened by the rapid extension of the methods of producing electrolytic chlorine. Dr. Lunge, no doubt, has it in contemplation to complete his picture by the republication, revised and enlarged, of the third volume of the former edition of his work, in which he dealt with what was then publicly known of the methods of carrying out the ammonia-soda process, as developed by the Solvays, their coadjutors and successors. The appearance of this volume will be awaited with great interest.

In its essential features this edition differs in no material particular from its predecessors. The plan of the original work is substantially unchanged. During a large portion of his long career as a technologist, Dr. Lunge was intimately associated with the practical conduct of the Leblanc process—a process which was nowhere more successfully worked than in England, which constituted, indeed, the chief of our chemical industries, and brought in the aggregate great wealth to those concerned in it. The quondam head of the chemical department of the famous school of technology at Zürich long ago constituted himself the historian of this time-honoured process, which, whatever the future may have in store for it, will always be accounted as one of the most considerable and important of the manufacturing methods of which chemical technology has any record. It occasionally happens that threatened processes, like threatened men, live long. We may express the hope, then, that the days of the Leblanc process are not numbered, and that Dr. Lunge may still long be with us to note and chronicle the changes which may come over it.

GEOMETRY AND ALGEBRA.

(1) *A New Geometry.* By W. M. Baker and A. A. Bourne. Pp. xxii+246+vi. (London: G. Bell and Sons, Ltd., 1911.) Price 2s. 6d.

(2) *Algebra. Part II., for the Use of Students preparing for the Intermediate and Previous Examinations of Indian Universities.* By Prof. K. P. Chottoraj. Pp. iv+486. (Simla, Calcutta: A. K. Chottoraj, 1910.) Price 1.12 rupees.

(3) *Parametric Coefficients in the Differential Geometry of Curves.* By Dr. S. Mukhopadhyaya. Pp. 31. (Calcutta: The University, 1910.)

(1) THIS text-book is an abbreviated and condensed form of the well-known work by the same authors published eight years ago, and therefore requires little comment. The suggestion made in the Board of Education circular on the teaching of geometry that propositions should so far as possible be taken in groups has been adopted. Thus theorems on parallels form the first, properties of a single triangle the second, tests for congruence the third, and constructions the concluding section of book i. The authors have throughout included considerably more material than is required by the Cambridge schedule, particularly in reference to proportion and areas. The last fifty pages of the book are devoted to solid geometry. The properties of line and planes are treated in a fashion very similar to Euclid XI.; this is followed by a number of properties of the tetrahedron, pyramid, cylinder, cone, and sphere. An excellent collection of examples on the mensuration of solid figures is included.

(2) The subject-matter of this volume ranges from quadratic equations to the exponential and logarithmic series, and in doing so covers more than four hundred closely printed pages. It is therefore evident that the treatment is very thorough. There is indeed far too much detail; all sorts of special and artificial cases are dealt with, apparently in order to fortify the student against every possible difficulty he may be likely to encounter. For those whose sole object is to pass examinations this may be advantageous, but on general grounds it is highly undesirable. The author has a lucid style, and has evidently arranged both the text and the examples with the greatest care. His book should be most useful to the teacher, but we are inclined to think it will be rather oppressive for the student.

(3) This pamphlet is the result of a series of investigations the author has made in differential geometry. The method of parametric coefficients was evolved from an attempt to obtain by elementary means expressions for the radius of curvature and aberrancy in terms of the arc. The first part of the paper deals with the properties of parametric coefficients of n-dimensions, and then applications are made to plane curves; these include the deduction of the equation of the osculating cubic and the general differential equation of the cubic. It is stated that additional applications will be found in a further paper by the author which will be published shortly.

MECHANICS AND TESTING OF MATERIALS.

(1) *Elements of Mechanics, with Numerous Examples for the Use of Schools and Colleges.* By G. W. Parker. Pp. ix+245. (London: Longmans, Green, and Co., 1911.) Price 4s. 6d.

(2) *A Handbook of Testing.* By Prof. C. A. M. Smith. Materials. Pp. xii+284. (London: Constable and Co., Ltd., 1911.) Price 6s. net.

(1) THIS book is intended for the use of students having only a comparatively elementary knowledge of mathematics; great care has been taken to ensure that the student should acquire thoroughly clear ideas of the first principles which form the groundwork of the subject, and this has been borne in mind in working out the numerical examples illustrating the various laws. The first part of the book is devoted to statics, the branch of the subject of perhaps the greatest importance to the engineer; composition and resolution of forces in one plane, moments of forces, parallel forces, couples and their composition, centres of gravity, and conditions of equilibrium are successively dealt with, and then the application of the laws, which have been deduced, to

the case of the so-called simple machines, all of them considered as frictionless, is taken up.

The last chapter of this section is devoted to an elementary treatment of the laws of friction, the rough inclined plane being used as an illustration. As a frictionless machine is a mere mathematical fiction, adopted probably with the idea of smoothing the path of the student, it is a pity that the author did not in the chapter on friction take one of the simple machines, say the screw, and show how materially such a formula as that deduced in the previous chapter for the relation of power to weight is modified directly friction is taken into account, and the problem changed from a mere exercise in applied mathematics to the practical question a young engineer is constantly called upon to face. It is doubtful if it is beneficial to students to set them to work out problems on frictionless machines.

In part ii. dynamics is taken up—velocity and acceleration; the laws of motion and their application to motion on rough planes, Attwood's machine, &c.; composition of velocities and accelerations are fully discussed. The last three chapters treat of uniform motion in a circle, work, and simple harmonic motion.

The author is to be congratulated on the excellent series of examples given at the end of each chapter.

(2) Laboratory work on the testing of materials forms an important part of the training given in engineering colleges at the present day, and many teachers and students have felt the need of a good text-book on the subject. Mr. Smith has done excellent research work on the effect of combined stress, and has devised ingenious strain-measuring apparatus for use in his researches, and he is now to be congratulated on having written a book which will be welcomed by all those who are engaged in the branch of experimental work known as the testing of materials, whether they are students just beginning to feel that they are entering upon a new field of fascinating work, practical men engaged in the daily task of commercial tests, or advanced students busy with research work upon one or other of the difficult problems which still require elucidation. The book is well illustrated, and the illustrations are so drawn that they show the essential principles of the machine or apparatus, a matter of great importance to the student who wishes to design similar appliances in connection with his own experimental work; the chapters on strain-measuring instruments and on alternating stress tests deserve special praise in this respect.

In the last chapter the author has given valuable advice and suggestions as to the best lines on which experimental work can be carried out in college laboratories, and a table of suitable experiments with notes as to the necessary apparatus. The book concludes with four appendixes, a bibliography, and a table of constants; the third appendix is devoted to a discussion on all the recent researches on combined stress, including the author's own work, and forms one of the best summaries which have yet appeared of the present state of knowledge on this important question.

T. H. B.

OUR BOOK SHELF.

General Index to the Monthly Notices of the Royal Astronomical Society, volumes liii. to lxx., 1892–1910, together with the General Index to Illustrations in the Memoirs, volumes i. to lix., and the Monthly Notices, volumes i. to lxx., 1822–1910; appendix, List of Comets, 1892–1910. Pp. viii+198. (London: Royal Astronomical Society, 1911.) Price 5s.

THIS index is one of fundamental importance to all workers in astronomy, and is a sequel to those previously published for vols. i. to xxix. and vols. xxx. to lii. respectively; it is hoped in future to publish general indices covering successive even periods of twenty years. The arrangement of the present volume from the annual indices prepared by Mr. Wesley has been carried out by Mr. Levander, under the general direction of the secretaries, and he is to be congratulated on the success attained.

Many of the headings have, by reason of the progress in astronomical work during the past twenty years, had to be rearranged or modified, and the changes are carefully explained in the preface. The present section dealing with the "Monthly Notices" takes up 168 pages, with something like forty references on each page, a tribute to the energy displayed by the authors of papers as well as to the completeness of the index.

Mr. Knobel has prepared the index to the illustrations, and this should prove exceedingly useful, as the items are arranged under subject headings, *e.g.* moon, planets, instruments, &c., the authors' names being given in approximately the chronological order of the papers.

Dr. Crommelin's appendix gives particulars of all the comets observed during the period 1892–1910, commencing with an apparition of Barnard's periodical comet in 1892, and ending with Brooks's second periodical comet 1910*d*. In view of the plenitude of comets during the present year it is interesting to note that the average number per annum, for 1893–1910 inclusive, works out at 4·7, the greatest number being 10 in 1898.

Many copies of the previous general indices remain in stock, and will be presented to such institutions and observatories as receive the "Monthly Notices," but have not the indices; application should be addressed to the assistant secretary.

Evolution, Life, and Religion: a Study. By the Rev. E. B. Kirk. Pp. 321. (Glasgow: John Smith and Son, Ltd.; London: James Clarke and Co., n.d.) Price 5s. net.

THE author of this book states his personal interpretation of cosmic and human evolution, which he considers from a philosophical and theological point of view. There has been material and spiritual progress from the simplest forms towards those of ever-increasing complexity, and the author interprets this as a continued expression of the Logos. He illustrates this by a fundamental diagram which he calls the "Logos-mirror." He has hold of the sound idea that scientific and intuitive interpretations must be regarded as complementary, not as antithetic, but his own personal equation bulks so large that it is difficult for the reader to get alongside of him. As it seems to us, Mr. Kirk intermingles different "universes of discourse" in a manner which is always unprofitable, as when he seeks to show that various fundamental doctrines of theology are expressions of fundamental laws of nature.

We have great sympathy with the proposition that "the mental continuity of creation in our world is as marked as the physical, and the lower

creatures are one family with the higher throughout," but we do not follow the author's theory of "spiritual inheritance" as opposed to "physical inheritance." Perhaps the right of making pronouncements regarding the scope of physical inheritance in garnering the past has not been earned by an author who tells us that "the human bowel is a worm." We do not mean, however, that this quaint sentence is in any way essential to the author's argument.

The Wanderings of Peoples. By Dr. A. C. Haddon, F.R.S. Pp. vii+12+5 maps. (Cambridge University Press, 1911.) Price 1s. net.

IN this little volume, one of the handy manuals issued by the Cambridge University Press, Dr. Haddon deals with the movements of the world's population from those times "when mortals knew no shores beyond their own" down to the modern movements in quest of political, social, or religious freedom.

The introduction deals with the general factors which determine the impulse and direction of migrations. The author also summarises the evidences for racial or cultural drift which are to be found in the physical characters of peoples, and in their artifacts, customs, folklore, and speech.

The main body of the work is a marvel of condensation. Into little more than one hundred pages Dr. Haddon has contrived to pack in terse and vivid phrases a whole history of the world so far as that history is correlative with ethnology and geography. Asiatic migrations and their sequence in Oceania are described in one chapter. Europe and Africa have each a chapter to themselves. The American peoples —North, Central and South—require for the history of their wanderings a space equal to two-thirds of that of the rest of the world together. One value of the book consists in the fact of its being an index to a more detailed examination of its subject. Each chapter is accompanied by its bibliography, and each paragraph is referred to its authority. For reference purposes the book is thoroughly up to date, and works appear in the bibliography which have appeared since its own chapters were in print. The five maps, owing to their small size, only show the more important migrations, but nevertheless they give a good general idea of the movements which have taken place on each continent. S. H. R.

The King to His People: Being the Speeches and Messages of his Majesty George V. as Prince and Sovereign. Pp. xviii+452. (London: Williams and Norgate, 1911.) Price 5s. net.

ONE of the most impressive characteristics of these speeches and messages is the remarkable manner in which the British Royal Family has been able to sympathise with, and be interested in, every aspect of the lives and enterprises of British subjects in all parts of the Empire. Whether addressing the Royal Society, speaking to school children, presiding at philanthropic meetings, officiating at military and other functions, his Majesty has shown a genius for speaking the right words at the opportune moment. The messages, "Wake up, England!" "Have Courage, Be Thorough," "The Rule of Science," and others, have served as an inspiration to workers throughout the Empire.

Probleme der Protistenkunde. By Prof. F. Doflein. II., Die Natur der Spirochaeten. Pp. vi+36. (Jena: G. Fischer, 1911.) Price 1.20 marks.

THE first of Prof. Doflein's studies, that on the Trypanosomata, was noticed in NATURE of June 24, 1909, p. 489. The present work deals with the Spirochaetæ, spirillar micro-organisms met with in ditch water and also in connection with many diseases, such as the relapsing fevers and syphilis, and as commensal parasites in the fresh-water mussel, &c. Some are doubtless vegetable in nature, but many must probably be regarded as belonging to the protozoa. From a critical survey of the minute structure of several species the author divides the spirochaetes into three groups: (1) Spirochaeta, with a central staining filament; (2) Cristispira, with a marginal staining filament; and (3) spirochaetes with a flattened band or lamella. He does not consider that sexually differentiated individuals have been proved to occur. The pathogenic forms, like many trypanosomes, are transmitted by blood-sucking arthropods, principally ticks. The essay is illustrated with many figures, and is a useful contribution to this important subject. R. T. H.

Arbeiten aus dem Gebiet der experimentellen Physiologie. Edited by Dr. Hans Friedenthal. Teil ii., 1909–10. Pp. viii+286+5 plates. (Jena: Gustav Fischer, 1911.) Price 5 marks.

THIS is a collection of twenty-seven papers which have previously been published in various German journals, or in the proceedings of scientific bodies. They have been carried out in Dr. Hans Friedenthal's private laboratory near Berlin, by Dr. Friedenthal himself and his colleagues. They represent a large amount of fruitful and painstaking labour, and relate to a great variety of subjects. The publication of collected papers from individual laboratories is often a great convenience to other workers, and Dr. Friedenthal is to be congratulated on his valuable output of the last few years. W. D. H.

The Process of the Year. Notes on the Succession of Plant and Animal Life. By H. H. Brown. Pp. 180. (London: Society for Promoting Christian Knowledge, 1911.) Price 2s. 6d.

THOUGH it does not appear to be his primary object, Mr. Brown has condensed much useful reading on nature-study into his volume. His "leading purpose is to show that the world is beautiful and happy." The year is divided into seven periods corresponding with the seven ages of man, and in each division a series of typical plants and animals is considered.

Philosophy. By Nicholas Murray Butler, president of Columbia University. Pp. vii+51 (London: Henry Frowde, 1911.) Price 4s. 6d. net.

THE third thousand has now been issued of President Butler's lecture, delivered on March 4, 1908, in the series on science, philosophy, and art, at Columbia University. The purpose of the lecture was, the preface points out, clearly to differentiate philosophy from science and "to cut away the odd and unfitting scientific garments in which some contemporary writers have sought to clothe philosophy."

Bergson. By Joseph Solomon. Pp. 128. (Philosophies Ancient and Modern.) (London: Constable and Co., Ltd., 1911.) Price 1s. net.

THE series to which this little volume has been added already included sketches of some fourteen systems of philosophy, but none of them formulated by a contemporary thinker. M. Bergson has been so much in the public eye recently that many readers will be glad to acquaint themselves with the teaching of this twentieth-century philosopher.

Confessions of a Robin. By Lieut.-Colonel A. F. Mockler-Ferryman. Pp. 192. (London: Society for Promoting Christian Knowledge, n.d.) Price 2s.

THIS story of incidents in the life of a robin will appeal to young children, who will not regard talking robins, with a well-developed power of consecutive thought, as incongruous. The tale reveals the author as a sympathetic observer of bird-life.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Relation of Big Game to Sleeping Sickness.

THE article by Sir Harry Johnston in NATURE of December 7 on "The Preservation of the African Fauna and its Relation to Tropical Diseases" gives a most admirable and sympathetic review of the subject; but there is one statement to which I must venture to take exception as not conveying, in my opinion, an accurate impression of the known facts of the case, namely, the following sentence:—"But within the last twelve months or so it has been proved conclusively by the biologists at work in Uganda that the large antelopes of that country are the hosts of dangerous trypanosomes, amongst others of the trypanosome which causes sleeping sickness."

So far as I am aware, this statement is based on the experiments reported by Bruce, Hamerton, and Bateman (Proc. Roy. Soc., B, 83, pp. 311–27), in which it was shown "that antelopes can be readily infected with sleeping sickness by the bites of artificially infected tsetse-flies" (p. 317), and that "the flies (*Glossina palpalis*) when infected by the virus of sleeping sickness obtained from the blood of infected antelopes are capable of transmitting the virus to susceptible animals" (p. 319). These results are based entirely on experiments conducted in the laboratory, and the authors state expressly that "positive evidence" is required "to complete the chain of evidence that antelope living in the fly-areas may act as a reservoir of the virus of sleeping sickness. *So far it has only been proved that they are 'potential' hosts*" (p. 325; the italics are mine).

The only instances known to me in which *Trypanosoma gambiense*, the trypanosome of sleeping sickness, has been identified as occurring in the blood of wild animals, naturally infected, are two in number, and in each case the animal was a monkey, and the locality Uganda; one such case is reported by Koch, Beck and Kleine (*Arbeiten k. Gesundheitsamte*, xxxi., p. 18); the second is reported by Bruce and his collaborators (Sleeping Sickness Reports, xi., p. 102). If there are other known instances of *T. gambiense* occurring naturally in wild animals, I should be glad to be informed of them; if there are not, however, it seems to me premature to state that antelopes have been proved to be the hosts of the trypanosome of sleeping sickness. If laboratory experiments have shown them to be the *potential* hosts of *T. gambiense*, the same can be said of many other animals which can be inoculated with this trypanosome in the laboratory. The following list of animals susceptible to *T. gambiense* is taken from Laveran and Mesnil, "Trypanosomes and Trypanosomiases," p. 382 (translated by Nabarro; Baillière, Tindall and Cox, 1907):—monkey (several species), lemur, dog, jackal, cat, rabbit, guinea-pig, rat, mouse, jerboa, hedgehog, marmot, horse, donkey, cow, goat. and sheep. This list is based chiefly on experiments performed in Europe, using European mammals or exotic animals in captivity, and there is no doubt it could be greatly extended by anyone experimenting systematically in the tropics on tropical animals; but as it stands it is sufficiently extensive, and indicates that a great many species of wild animals, small or large, might be incriminated as potential hosts of *T. gambiense* equally with the antelopes, and that the destruction of the "big game" alone would be likely to produce very little amelioration, if any, in the conditions.

The whole history of sleeping sickness in Uganda indicates that the disease has been imported from the west by human agency (compare Laveran and Mesnil, *op. cit.*, pp. 359–66), and that man is the primary host of the trypanosome, at least in Uganda. If, however, the parasite has now been transmitted from man to other susceptible animals by the tsetse-flies, there is no reason to repard the antelopes or other big game as having monopolised the functions of being "reservoir" hosts of the virus. From the point of view of preventing the infection from spreading from animals to man, domestic animals would seem to be a much greater danger as a reservoir of the virus than antelopes and creatures the natural instincts of which impel them to keep at a distance from the haunts of human beings.

If, therefore, it is desired to extirpate the potential hosts of *T. gambiense* in regions where sleeping sickness is rife, it would not be sufficient to destroy the big game; it would be necessary to convert the whole country into an uninhabited and lifeless desert. In my humble opinion this method of preventing the spread of sleeping sickness is a futile one, and not likely to yield useful results. I believe that there is only one practicable method of interrupting the transmission of the trypanosome, and that is by measures calculated to destroy or keep down the tsetse-flies. At the present time the most urgent need is more knowledge of the bionomics of the species of Glossina and of their natural enemies. Some years ago I made the suggestion in NATURE (November 8, 1906) that fowls, wild or domesticated, would be likely to be efficient in keeping down the flies by scratching up their pupæ and eating them, but, so far as I am aware, no experiments have ever been carried out to put this notion to the test. So long as sleeping sickness cannot be made amenable to treatment, attention must be concentrated on prevention, the central problem of which, in my opinion, is the destruction of the insects concerned in the transmission of the disease.

Lister Institute of Preventive Medicine, Chelsea Gardens, S.W., December 9.

The Inheritance of Mental Characters.

THE reply of Dr. C. Walker to Dr. Archdall Reid in your issue of last week seems to me somewhat quibbling, and suggests that he is not intimately acquainted with Prof. Pearson's Huxley lecture. The particular part of this lecture quoted by Dr. Reid, and referred to by Dr. Walker, reads actually as follows, the italics being Prof. Pearson's own:—". . . We have found the *same* degree of resemblance between physical and psychical characters. That *sameness* surely involves something additional. *It involves a like heritage from parents.* The degree of resemblance between children and parents for the physical characters in man may be applied to the degree of resemblance between children and parents for psychical characters. We inherit our parents' tempers, our parents' conscientiousness" (not *consciousness*, as printed in Dr. Reid's quotation), "shyness, and ability, even as we inherit their stature, fore-arm, and span."

Now surely Dr. Walker cannot justly charge Dr. Reid with misinterpreting Prof. Pearson's statement in this instance, where Dr. Reid apparently infers from the words "*a like heritage*" that Prof. Pearson meant "*inherited in the same way*"; and that the words "*a like heritage*" implicitly connote in this context an actual identity of the modes of *transmission* and *reproduction* of a parent's "conscientiousness" with those of the transmission and reproduction of a parent's fore-arm. Nor, it seems, would it be unfair to impute, on this ground, to Prof. Pearson the doctrine that external influences brought to bear on the child, such as experience of the world, training, example, &c., could not have any greater effect on his ultimate "conscientiousness" than any external influences could exert on the ultimate length of his fore-arm.

London, December 10. H. BRYAN DONKIN.

I THINK Dr. Walker is scarcely clear as to the situation. A personal acquaintance with a writer is not necessary when we judge his published opinions. By "character" biologists mean any trait of a living being—a head, a hair, a characteristic of a hair, a characteristic of that characteristic, and so on. Of course, no character of any sort—neither a head nor a scar, for example—can develop in the individual unless the potentiality to develop it under fit conditions is antecedently present. If, then, we think in terms of germinal potentiality, all characters, for example heads and scars, are equally inheritable. But biologists commonly apply the term "acquired" to actual somatic characters which have developed under the influence of use or injury, the term "inborn" to characters which

developed in the absence of these influences, and the term "inheritable" to characters which were present in the parent and tend to be "inborn" in the offspring. Thus they speak of heads as inborn and inheritable, and of use-callosities and scars as acquired and non-inheritable. I am not concerned here with the correctness of these terms. My statement of the manner in which they are used is correct.

Prof. Karl Pearson employs the term "inherit," but not, to my knowledge, the terms "inborn" and "acquired." Instead, he uses "bred" and "created," which apparently are intended to mean the same. He has not, I believe, defined any of his terms Presumably, therefore, he uses them with their ordinary meanings. If he does not, then not only have I been mistaken, but also almost everyone else, including such a careful thinker as Sir Ray Lankester. In that case, what is the meaning of the expression "bred, *not* created"? Is potentiality meant here? The italics are mine.

Even in the absence of statistical inquiry, it is a common conviction that individuals tend to resemble their progenitors mentally as well as physically. Thus the offspring of a vertebrate is another vertebrate, of a man another man, of a Hottentot another Hottentot, and so on. But individual characters are less certainly inherited than varietal characters, varietal characters than specific characters, and so on. Prof. Pearson's work concerns only individual characters (*i.e.* variations); but he makes—not once but repeatedly, not only in scientific memoirs but also in popular lectures and letters to newspapers—the *unqualified* statement that the mental and physical characters of man are inherited at the same rate. It seems that this rate is "somewhere about 0·46 to 0·50." His estimate, if it led nowhere, would have no more importance than, for example, a calculation concerning the average length of noses. But it leads him somewhere—to the notion that the moral and intellectual qualities are "bred, *not* created," instead of to the notion that they are bred *and* created. It leads him to a false opposition between "nature" and "nurture," instead of to the really quite obvious truth that the nature of man, the educable animal, is such that he is supremely responsive to nurture. It leads him to the notion that the poorer classes in England are, on the average, by nature inferior to their more fortunate compatriots, and thence to dire predictions concerning our future as a nation and to demands that something shall be done. It would lead him, I suppose, to the notion that an English baby, reared by African cannibals, would, when grown, resemble his progenitors and differ from his educators as much mentally as physically. And so on and so forth. No one, I suppose, disputes that individuals vary in capacity. The dispute, in the case of the moral and intellectual traits, is entirely as to whether capacity can become more than mere potentiality unless nurture plays its part as the other blade of the scissors. In other words, the dispute is as to whether these traits are or are not acquirements, that is, products of man's educability *plus* his individual experience.

The biometric plan of ascertaining correlations between variations, and thence surmising a causal connection, is not, as is commonly supposed, a new instrument in the hands of men of science. It is merely a variant of the very old method of concomitant variations which is described in almost every book on logic and in almost every work on the methods of science. There is, however, this difference: according to the method of correlated variations as exemplified by biometricians, if two things vary together *on the average*, there is *invariably* a causal connection between them; according to the method of concomitant variations as described by logicians, if two things *invariably* vary together, there is *probably* a causal connection.

In my letter I stated that Dr. Walker had reproduced some of my opinions in his book almost in my own words. I should have added that he made very full acknowledgment.

G. ARCHDALL REID.

Southsea, December 10.

IN Dr. C. Walker's quotations (NATURE, November 23 and December 7) from Dr. A. Reid's paper, Prof. Karl Pearson is represented as saying: "We inherit our parents' tempers, our parents' consciousness," &c.; this should read: "We inherit our parents' tempers, our parents' *conscientiousness*," &c. (see Journal Royal Anth. Inst., vol. xxxiii., p. 204).

E. LAWRENCE.

"Kama," Sunningdale Avenue, Westcliff-on-Sea, December 11.

Temperature of the Upper Atmosphere.

MESSRS. GOLD AND HARWOOD in their paper on the present state of our knowledge of the upper atmosphere, printed in the British Association's reports for 1909, give a table showing the mean temperatures for the months of the year at heights varying from the surface to 15 kilometres. With regard to it they say the principal feature is the very marked minimum in March and the small, though less marked, effect in September. The table is based upon about 5800 readings taken at Strassburg during five years. With the aid of this table I have plotted on the accompanying diagram the temperatures at various

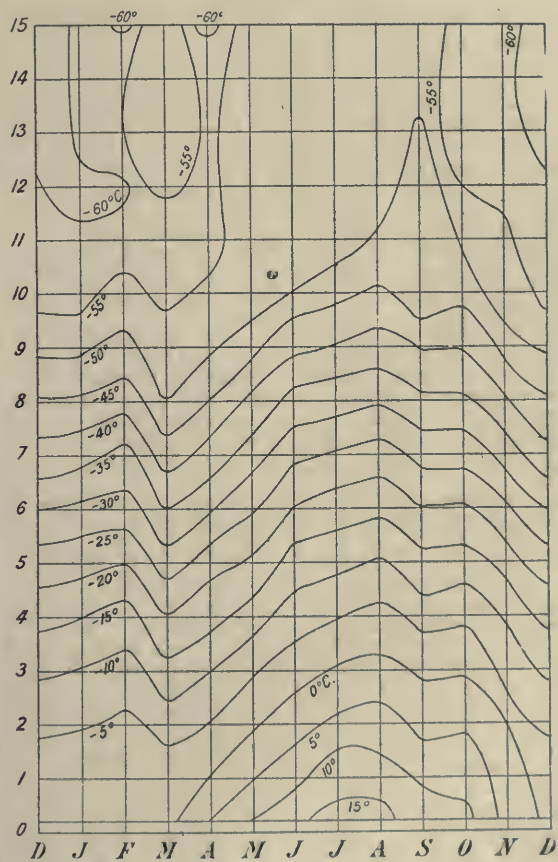

FIG. 1.—Temperature variations throughout the year at different heights.

heights (isotherms). Plotted in this manner, a result is obtained which shows clearly that a check in the fall of temperature takes place between September and October. The principal feature, however, is the rise of temperature between December and February, and the small gradient of temperature below 2000 metres during those months.

The tracing of the isotherms in the advective layer presents some difficulties, owing to the abnormal conditions prevailing in it. It would appear that during December a low temperature condition prevails, and appears to die away from the top downwards, disappearing at a height of about 12,000 metres in February. In March there is a marked inversion of temperature between 12,000 and 15,000 metres which does not seem to continue into April.

Between April and May, however, the isotherm of $-55°$ passes into the upper atmosphere, where, comparatively speaking, warm conditions prevail in the advective layer from May to September. As this method of plotting the results shows clearly the temperature variations throughout the year at high levels, I thought the diagram might be interesting to your readers. R. M. DEELEY.

Inglewood, Longcroft Avenue, Harpenden.

The Weather of 1911 and the Ultra-violet Radiations of the Sun.

IN connection with Dr. Shaw's attempt to explain the remarkable weather of this summer (NATURE, November 30), I should like to direct attention to a point of view which in general, but especially in the past summer, deserves the attention of meteorologists. My remarks are based on a series of experiments which I carried out, together with Prof. Lenard (P. Lenard and C. Ramsauer, "Über die Wirkung sehr kurzwelligen ultraviolleten Lichtes auf Gase und eine sehr reiche Quelle dieses Lichtes," Heidelberger Akademie, five parts, 1910–11).

Dr. Shaw states that all conditions necessary for a heavy rainfall appeared to be present, without rain falling. But he has not paid attention to an important condition: for the production of rain nuclei must be present, which can serve as centres of condensation when all other necessary conditions are fulfilled. The absence of such nuclei is in my opinion the chief cause of the remarkable weather of this year.

In the work just quoted we have clearly separated, for the first time, the different actions of ultra-violet light on gases, and explained the complicated effects due to their simultaneous existence. We distinguish three actions of ultra-violet light on dust-free gases:—

(1) The formation of electrical carriers of molecular size, caused by selective absorption of the light; the power which these carriers possess of producing condensation is, according to our experiments, very small compared to that of the nuclei, originally neutral, mentioned under (3).

(2) Chemical action, *e.g.* formation of ozone in oxygen; this effect is connected with but small absorption of the light.

(3) Formation of condensation nuclei, *i.e.* formation of solid or liquid products by the direct action of the light on the gases; *e.g.* formation of drops of hydrogen peroxide from water vapour, as found by Mr. C. T. R. Wilson, or by subsequent reaction of the products formed with the other components of the air, *e.g.* formation of ammonium nitrate and nitrite from ozone and ammonia. The size of these nuclei depends on the intensity of the light and their time of formation. Their chief property is their great power of acting as centres of condensation, and the larger they are the more active in this respect. They possess *originally* no electric charge, but easily acquire one if carriers of electricity are simultaneously produced by coming together with these; the presence of a charge has no effect on their power of acting as condensation nuclei.

This gives us the chief source of nuclei in the earth's atmosphere. If we neglect the purely local formation of nuclei in large centres of industry, then the ultra-violet, and to a minor degree the kathode, radiation of the sun is chiefly responsible for the nuclei which are meteorologically so important. This production of nuclei extends from the uppermost down to fairly low-lying layers of the air, as the active rays are only absorbed to a small extent, and is chiefly conditioned by the amount of oxygen and ammonia present.

Thus the lack of nuclei, and the consequent fine weather of this year, can be attributed to a much diminished ultra-violet radiation of the sun. This is in accord with the now existing minimum of general activity of the sun, as characterised by the minimum of sun-spots and northern lights. This view is not contradicted, but confirmed, by the high temperature on the surface of the earth, as this is principally conditioned by the increased clearness, *i.e.* transparency to heat radiations, of the atmosphere.

CARL RAMSAUER.

Radiologisch-Physikalisches Institut, Heidelberg, December 9.

"Draysonia."

IN NATURE of November 16 you have done me the honour of inserting a review of my book "Draysonia." As the reviewer appears to have been under some misapprehension, I beg you will in justice do me the favour of inserting a few words of explanation.

I am well aware of my inability to do full justice to the late General Drayson in attempting to bring his theory under public notice. But it is evident that your reviewer, after perhaps a hasty glance at "Draysonia," has not considered it worthy of close perusal; otherwise he would scarcely have assumed that a naval officer who has had the "Nautical Almanac" in use for more than seventy-one years (and has made nautical astronomy an occupation and recreation) "confuses precession with aberration," and is therefore "scarcely fitted" to deal with the subject.

Your reviewer may possibly be a professional astronomer (who perhaps dislikes anything unorthodox and not in accordance with the text-books), and, if so, he will be aware that in the later "Nautical Almanacs" the word "precession" in the catalogue of stars has been substituted for the old and better term "annual variation," which was used in the "Nautical Almanac" and by our old astronomers for as many years as I can remember up to 1894 or 1895, when the change was made. Previous to this the word precession had been mainly confined to precession of the equinoxes (dealt with in section 6 of "Draysonia"), which at present is about 50″ and is totally distinct from what astronomers term aberration, but which I prefer to call annual motion of the pole.

Your reviewer further states that I have computed the precession of many stars by Drayson's method, and that, if this proves anything, it proves the correctness of the "Nautical Almanac." This is a mistake and is an inversion of my process. Instead of having, as he stated, calculated the so-called precession of many stars, I have used the precessions, so accurately given in the "Nautical Almanac," in order to find therefrom the amount of the annual motion of the pole; and I have shown that the so-called annual precessions of the stars, all varying in amount and direction, both in right ascension and declination, are exactly accounted for by one single movement of the pole of about 20″, which produces the apparent annual precession as obtained by observation and recorded in the "Nautical Almanac," the accuracy of which I have never impugned.

I am unable to understand why your reviewer questions my statement that Mr. Stone, the late Radcliffe observer at Oxford, made the error of sidereal time erroneous to the extent of 41·51s. in 1892. A reference to the Royal Astronomical Society's notes of March, 1894, will show that I am correct. ALGERNON DE HORSEY.

Melcombe House, Cowes, November 19.

I AM quite willing to admit that I have misunderstood the gallant Admiral, and accept unreservedly his statement that he does understand the difference between precession and aberration. In my own defence you will perhaps permit me to quote the passage which misled me.

"Possibly I shall be told that I have found a mare's nest, and that it has been known all along that the right ascension of a star and its annual precession in declination are functions of the annual motion of the pole, and that such motion can be found in the 'Nautical Almanac,' *and is properly termed aberration.*"

The italics are mine. To my mind this sentence admits of only one construction; and, if I have been so unfortunate as to misconstrue it, I have no doubt I have not correctly apprehended the author's meaning in other places, and therefore it is of little use to discuss the several points raised. THE REVIEWER.

Dust Explosions.

PROF. GALLOWAY's brief article on dust explosions in NATURE of November 30 is very timely; but readers of it would receive the impression that the true cause of the explosion at the Tradeston Flour Mills, Glasgow, in 1872, was first made known in the report of Profs. Rankine and Macadam. This is not the case: the fact that flour-mill ex-

plosions are actually dust explosions was first stated in England by Mr. Watson Smith, editor of the Journal of the Society of Chemical Industry, in a letter which appeared in *The Glasgow Herald* on July 12, 1872, immediately after the Tradeston disaster. The priority of Mr. Watson Smith was recognised at the time by the Royal Society of Edinburgh, and later (in 1882) by Sir Frederick Abel in a lecture at the Royal Institution.

It is interesting to know that nearly six years ago Mr. Watson Smith read a paper at Liverpool (the scene of the latest dust explosion) in which stress was laid on the fact that any kind of carbonaceous dust might, under certain conditions, become a source of danger (see Journn. Soc. Chem. Ind., January 31, 1906).

ALBERT SHONK.

10 Dartmouth Road, Hendon, December 5.

I MUCH regret that I had entirely forgotten the fact, stated in Mr. Shonk's letter, that Mr. Watson Smith had attributed the disaster at the Tradeston Flour Mills to an explosion of dust in a letter to *The Glasgow Herald*, published before the report of Profs. Rankine and Macadam appeared, or I would certainly have mentioned it in the article referred to.

W. G.

The Feeding Habits of Crepidula.

WITH reference to the note on Crepidula in NATURE of December 7 (No. 2197, p. 187) it may be of interest to your readers to know that during some recent researches on this animal I have been able to confirm the necessity for investigating how far the presence of the slipper-limpet (*Crepidula fornicata*) is a menace to successful oyster-culture on the Kent and Essex coasts. It has been believed by various naturalists that Crepidula takes the same kind of food as the oyster, but on this point there exists no definite information. During an investigation of this matter I discovered the manner in which the animal feeds, from which there can be no doubt whatever as to the nature of its food. The mode of feeding in Crepidula is the same in principle as that of the oyster, that is, there is an ingoing and an outgoing current of water kept up in the mantle-cavity, while between the two currents the gill acts as a strainer, retaining even very fine particles of suspended matter, which eventually—by one of two ways—reach the mouth.[1]

Thus it is established beyond doubt that Crepidula feeds on the same material as the oyster, that is, on the food-material found on or floating near the sea-bottom, and the danger apprehended from this intruder is confirmed: Crepidula is competing successfully with the oyster for food and space. Whether there is enough food and space for both Crepidula and oysters is another matter which must be determined by local researches. Thus the problems for the Kent and Essex oyster-farmers are to keep up the food supply of oysters and to reduce the numbers of Crepidula and the many other animals which take the same food as oysters.

J. H. ORTON.

Marine Biological Laboratory, Plymouth,
December 10.

[1] It is proposed to publish a full account of how Crepidula feeds in the next number of the Journal of the Marine Biological Association.

Tadpole of Frog.

AT the beginning of April last I collected some frog ova for the purpose of making observations on development. Tadpoles appeared about April 9, and from time to time from that date until July 17, when young frogs were developed, I took batches away for preservation and sectioning. On July 17 only one tadpole was left of the original stock, and that one, though in water out of doors and with a supply of waterweed, has not developed farther, but is a tadople still and is still alive. Some years ago I had a similar case with a frog tadpole. Can any of your readers suggest the reason of this phenomenon?

T. PLOWMAN.

Nystuen, Bycullah Park, Enfield, December 8.

MICROKINEMATOGRAPHY.

WITHIN the last few months we have been shown a new appplication of the kinematograph, which indicates yet another stage of technical attainment, and another field in which it may supplement our knowledge. Its range has been extended to the representation of objects as seen through high powers of the microscope. Apart from any positive increase to knowledge which may be obtained by its means, this is a technical achievement of a very high order. In the usual microscopic preparation it is impossible to obtain a high degree of illumination, and the greater the magnification the less the illumination becomes. It is only by artificially increasing the contrast by means of stains and so forth that we can obtain a clear differentiation of even a motionless object. To take in one minute some thousands of successive photographs of a living, unstained object, magnified six hundred or a thousand times, an object, moreover, which is moving rapidly, and therefore continually altering its focal plane, is a task which might easily seem impossible.

M. Comandon, however, has succeeded in this extremely difficult problem. The illumination-difficulty he avoided by using what is known as the ultra-microscope or dark-ground illumination, in which the object is seen against a black background, being lit itself by rays of light striking it from the side, and thence deflected upwards towards the lens of the microscope. This method gives an extremely brilliant contrast-illumination of the outlines of the object against a black ground and makes it possible to take on a properly sensitised film photographs of exceedingly short exposure. The resulting picture naturally shows comparatively little of the internal structure of the object under examination; the bulk of the rays of light are deflected from its surface. But it is surprising how much does appear. The nucleus of a cell, for example, is frequently quite distinct, and some structures, such as the kineto-nucleus of a trypanosome, can sometimes be seen perfectly clearly and be followed as the organism moves from place to place. A large number of films prepared under the direction of M. Comandon has been exhibited during the present year by Messrs. Pathé Frères, and the realism and vitality of these kinematograph pictures can scarcely be imagined by anyone who has not seen them thrown on the screen.

An interesting film is one which displays the blood actually circulating in the vessels of the living body. The preparation, which is from the tail of the tadpole, shows a number of tiny blood-vessels, which measure about one-hundredth part of a millimetre in diameter. Crowded together in the larger of these, the individual corpuscles of the blood can be seen to pass out one by one into minute branches, for which they seem almost too large, and within which they make their way here and there through the surrounding tissue, not apparently without occasional difficulty. Even in the larger vessels, along which the bulk of the corpuscles are hurrying, the rate of progress varies considerably, and the direction may actually be reversed for a time and the blood apparently flow backwards. The coloured corpuscles of the blood, from which it derives its red tint, have, of course, no independent motion of their own, and are simply carried along by the stream in which they are suspended. But the colourless cells or leucocytes have such independent motion, and in another film we are shown a white cell gradually altering its shape, throwing out a long filament into which the rest of the corpuscle slowly flows, until the whole cell has altered its posi-

tion and moved from one place to another. By aid of this motion these leucocytes are able to fulfil one of their best-known functions, which is to act as

FIG. 1.—Series of pictures of normal human blood. From a kinematograph film.

FIG. 2.—Amœboid movement of leucocytes.

FIG. 3.—Trypanosomes in the blood.

FIG. 4.—Spirillosis of fowls.

FIG. 5.—Relapsing fever.

scavengers of the vascular ways of the body, and to take up into themselves abnormal substances with which they come in contact, whether microbes, diseased cells, or granules of inert matter; and this process is illustrated for us by a series showing the gradual surrounding and ingestion of a red corpuscle by a white cell. This is the phenomenon of phagocytosis, which has of late been brought so prominently before the public in its relation to the cure of infectious disease.

That such abnormal substances may occur in the blood is shown in a beautiful series of pictures of its condition in relapsing fever. After we have been made familiar with the appearance of normal blood, in which the red corpuscles appear as brilliant rings and the larger white cells as cloudy masses with shadowy nucleus and brightly shining granules, we see the blood as it may appear at the height of an attack of the disease. It is now full of foreign organisms, long, slender spiral threads, which dart hither and thither upon the screen, now hooking themselves together and again disentangling themselves, impinging on the red cells and recoiling in amazing numbers and activity. The whole blood history of an attack is shown on these films, from the interval between the crises when no organisms are present, through the period of multiplication to the termination of the attack with the tendency of the spirals to aggregate together and eventually disappear. Several such blood-pictures may be seen, including a most beautiful preparation of an infection with a trypanosome, a close ally of the organism which produces sleeping sickness. Here the parasite is seen in quite perfect distinctness, swarming in enormous numbers in a drop of blood with an incredible activity and energy of motion.

Technically perhaps the greatest triumph of these microkinematograph pictures are the films which show us the *Spirochaeta pallida*, the causal organism of syphilis. This delicate thread, with its many tiny spirals, is so exceedingly minute that even when motionless and stained it is difficult to see with the best of ordinary microscopes. But here it appears alive and moving, with its coils all clear and sharp, a perfectly distinct picture. Only those who know the careful pains, which are necessary to obtain a satisfactory demonstration of this tiny object, can fully appreciate the skill which has gone to the making of such photographic films as these.

We have dwelt chiefly upon the microscopic preparations which Messrs. Pathé Frères have exhibited, because they seem to us the most remarkable of those

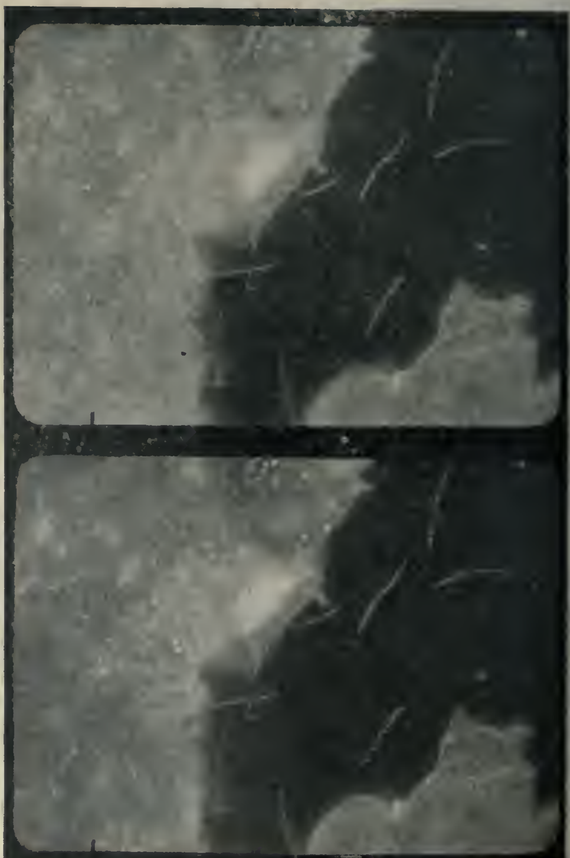

FIG. 6.—Spirochæta of Syphilis (from the cornea of the eye) enlarged.

which we have seen. But there are many other applications of kinematography to biological subjects

which are of great interest and value. Many movements in nature proceed at a rate such that we cannot successfully follow them with the eye and brain. The slow movements of a leucocyte, the gradual unfolding of a flower-bud or upward growth of a plant advance so leisurely that we cannot readily follow the change—it is only by observing them from time to time that we can appreciate that alteration is occurring. A succession of photographs, however, taken at considerable intervals, and passed rapidly in review before us, shows us as occurring in a few minutes the whole process which may take hours or days in reality, and we are better able to appreciate the nature of the phenomena because the sequence becomes more obvious. Conversely, many motions occur too fast for us to analyse them. The fact that our retina can clearly distinguish only impressions which reach it at a comparatively slow rate makes it impossible for our unaided eye to follow the sequence of many natural phenomena. By reproducing at a slower pace the changes which do occur, the kinematograph can assist us to attain a clearer perception of the nature of the alteration which is taking place, or, even if we are still unable to grasp the successive phases, a study of the film itself will enable us to follow the sequence and analyse the motion with a greater detail and a greater accuracy than any number of examinations of the natural phenomenon can possibly supply. The kinematograph therefore can give us a positive addition to the sum of our knowledge, as well as diffuse through wider circles knowledge already gained.

This latter, while perhaps the most obvious, is not the least of the functions which such moving pictures can fulfil. There are thousands of people in this country who are intimately acquainted with the cellular constituents of the blood, and their various shapes and functions, thousands who have seen the ordinary bacterial preparations or are familiar with the heart-beat and its action on the pulse, but of these thousands not one-tenth have actually seen the amœboid movements of a leucocyte or a spirillum wriggling its way between the corpuscles or the heart itself beating before their eyes. Yet these are things which it concerns them to understand, and no amount of imagination can supply the clearness and comprehension which actual seeing can give. The kinematograph might well become a most efficient aid to the teaching of very many biological, and especially medical, subjects.

The accompanying illustrations have been reproduced from kinematograph films kindly supplied for the purpose by Messrs. Pathé Frères.

THE RUBBER-PRODUCING PLANT OF THE MEXICAN DESERTS.[1]

AMONGST the botanical collections formed in 1852 by Dr. J. M. Bigelow, whilst attached to the Mexican Boundary Survey, were specimens of a shrub known to the Mexicans as "guayule," afterwards described by Prof. Asa Gray as *Parthenium argentatum*. No mention, however, was made of its rubber-bearing qualities. It was not until 1876 that public attention was directed to guayule rubber by an exhibit sent to the Centennial Exposition at Philadelphia in that year. The country peon had, it appeared, for long been in the habit of making playing balls and other articles by the "communal mastication" of the bark of this shrub, and it was by that means sufficient was obtained for the above-mentioned exhibit. Investigation showed that the plant was capable of producing in the neighbourhood of ten per cent. of its weight of dry rubber, and that it grew in vast abundance in the desert country of northern Mexico.

FIG. 1.—Foot-slope of Sierra Zuluaga.

This discovery speedily changed the economic value

[1] "Guayule (*Parthenium argentatum*, Gray), a Rubber-plant of the Chihuahuan Desert." By Prof. F. E. Lloyd. Pp. viii+213+46 plates. (Washington: Carnegie Institution, 1911.) Publication No. 139.

of these deserts, and set in motion business operations involving millions of capital based upon the amount of raw material in sight. In 1902 chemical and mechanical extraction plants were set up, and guayule rubber, though an inferior article containing a high percentage of resinous substance, soon became a very important item in the imports of the United States. At the present day the outlay of American capital in Mexico alone is said to amount to 30,000,000 dollars.

A good deal has already been written dealing with guayule, but the monograph by Prof. F. E. Lloyd is a most welcome addition to special rubber literature. Its contents are the outcome, Prof. Lloyd states in his preface, of an investigation carried out by others and himself at the instigation of certain Mexican rubber companies towards the elucidation of the question of the profitable cultivation of guayule in the desert with a view to future maintenance of supplies.

In addition to the physiology of the plant under and Prof. Lloyd estimates that existing supplies will be exhausted in a few years' time. Seed can be germinated and plants easily raised by giving a small amount of shade and subsurface irrigation. On p. 121 the author remarks that "the most fundamental economic question for which an answer will be sought in these pages is that relating to the production of rubber under irrigation." In searching for a reply one has to be content with the statement that "The less the water the thicker the bark (cortex) and *vice-versa*." Irrigated plants naturally grow more vigorously but produce wood at the expense of cortical tissues, and it is largely the latter from which the rubber is extracted.

The book is evidence of a vast amount of labour undertaken in the spirit of enthusiasm, but its utility for the general reader is curtailed by the want of condensation in dealing with experiments and tabular results, and the absence of definite statements or deductive conclusions. It is elaborately illustrated by photo-litho plates, containing a large number of photo-

FIG. 2.—Guayule in a very dense growth.

varied conditions, the main subjects dealt with are questions of climate and soil, seed germination, methods of reproduction, results of cropping, environment of the plant, its rate of growth, methods of extraction, the possibility of maintaining the supply by irrigation, and the effects of this upon the yield of rubber. In the course of the investigation attempts are made to throw light upon many interesting problems in connection with the physiology of desert vegetation.

Much attention has been given to the formation of resin and rubber, and the close connection between the two. There appears to be no tube-like laticiferous system as in other rubber-yielding plants, the rubber being formed apparently in the cells of the resin-canals, whilst the resin itself is found only in the canals and not in the cells.

The guayule shrub is a very slow grower, a fifteen-year-old plant being no more than 15 inches in height,

graphs and line-drawings of the minute histological structure of the different parts of the plant, as well as by some fine photographs of desert surroundings.

THE AËRONAUTICAL BLUE-BOOK FOR 1910–11.[1]

THE specific questions which form the subject of the experiments and observations described in this report may be briefly described as follows:—

The deviation of air resistances from the law of proportionality to the square of the velocity and the effects of friction in this connection—discussed theoretically by Lord Rayleigh and experimentally by Messrs. Bairstow, Booth, Dr. Stanton, and Mr. Pannell.

[1] Technical Reports of the Advisory Committee for Aëronautics for the Year 1910–11 (with Appendices). Pp. 134. (Published by his Majesty's Stationery Office. London: Wyman and Sons; Edinburgh: Oliver and Boyd; Dublin: E. Ponsonby, Ltd., 1911). Price 6s.

Theorems on stresses in envelopes by Mr. Booth.

Forces and couples on a model dirigible placed obliquely to the current by Mr. Bairstow.

Air resistances of wires and ropes, both stationary and vibrating, by Mr. Melvill Jones and Dr. Stanton.

Air pressures on the honeycombed radiator and Paulhan girder.

Methods of observing flow of water past an obstacle by Mr. Eden.

Propeller experiments by Mr. Bairstow.

Tests of balloon fabrics.

Meteorological apparatus by Mr. J. S. Dines.

The present report is characterised by greater definiteness of purpose than was noticeable in its predecessor for 1909–10. Many of the papers have a direct bearing on aërial navigation, and we do not exclude Mr. Bairstow's experiments on square plates altogether from this category, since if it is required to test the deviations from the law of proportion of pressure to square of velocity, the first tests may as well be made on square plates as on any other kind of surface. The experiments on obliquely placed model dirigibles also have an important bearing on the problems of stability and steering as applied to airships, and the necessity for such investigations is fairly evident. At the same time, the superfluity of diagrammatic details which was referred to in the review of the preceding year's report is also to some extent a conspicuous feature of the present volume, and it again appears desirable to direct attention to the fact that some of these are wholly unnecessary and only occupy space that could be with greater advantage devoted to broad and general discussions by the members of the committee on the principles of mechanical flight, considered in relation to the experiments here described. The three and one-third pages of description of Mr. Dines's theodolite would probably be just as useful without the three folded diagrams, one taken at Pyrton Hill in a clear sky, and one showing the observations by Cary at station A, and Bosch at station B, up to the point where a certain pilot balloon was lost sight of.

The article on propellers, while accompanied by six bulky folding plates, only occupies four pages of letterpress. One of these is devoted to "improvements in apparatus"—not improvements in propellers, but in the dynamometers and other instruments for testing them, while the remainder are principally devoted to determining the constants and coefficients of a Vickers and Maxim, and three Ratmanoff propellers. Certain conclusions are stated, referring in particular to the effects of cutting down the blade area, and the extent to which the principle of similarity can be applied to models. But surely there is a great deal more to be said about the general problem of propeller action, even in connection with the interpretation of the results of these experiments, and it is desirable that the investigation should be extended to other types of propeller than the two here discussed. Perhaps this will be done another year.

In making these criticisms it is necessary to guard against one serious mistake which is commonly made, and does much to retard scientific progress and development. It is frequently said of certain physical investigations that they are of no use because they do not take into account all the disturbing factors which exist in nature. As applied to aviation, we are told by some people that it is no use to investigate the efficiency of planes and propellers by laboratory experiments, as the investigations fail to take account of the atmospheric disturbances which affect the motion of an actual aëroplane. This, however, is equivalent to saying that we require to know less about the efficiency of our apparatus under the complex conditions prevailing in nature than we should if the conditions were simpler. In reality we ought to know *more*, and experiments made under ideal conditions instead of being condemned as "unnecessary," should be described as "insufficient," and should therefore be pushed on with all possible haste as a preliminary step to investigations of a more general character.

In view of the desirability of using experiments with models for all they are worth, and the success which has attended such experiments in naval architecture, it is satisfactory to find that the principle of dynamical similarity is receiving considerable attention. At the same time, one has rather an idea that the atmospheric conditions under which aëroplanes and dirigibles are navigated are rather different from those existing in the National Physical Laboratory, and the idea suggests itself that, instead of trying to produce a current of air that shall be as nearly uniform as possible, results equally interesting would be obtained if it were attempted to do the very opposite thing. When so many physical data are unknown even to within 100 per cent., it surely is rather unnecessary to trouble about whether a velocity of 1·6 or 2·1 miles an hour is set up in the air when a rotating arm is travelling through it at thirty-five miles an hour. A study of the "wash" or interference effects caused by planes or propellers on other planes or propellers following in their wake would be more useful. For example, the lift and drift of the isolated Paulhan girder determined on p. 36 may for this reason be different from the values which they would have when the girder occupied its proper place in an actual flying-machine.

There are two possible alternatives. One is (following the usual custom) to disparage such researches as those last-named; the other is to ask for something more. The latter alternative certainly appears from every point of view to be the better.

The collection of abstracts of papers on aëronautics, compiled from various English and foreign journals, extends from p. 92 to p. 124, and is an exceedingly valuable feature of this, as it was of last year's report. The preparation of such abstracts involves an expenditure of time and thought, on the part of the abstractors, which, as a rule, receives but scanty recognition. The idea suggests itself whether some working arrangement could be arrived at between the Government Committee and the Aëronautical Society to enable the abstracts to be reprinted in the Journal of the latter, and thus circulated among its members at regular intervals. Perhaps this question may be deferred until the Aëronautical Society has had time to settle down after the arduous work of reorganisation on which its council has recently been engaged.

SIGHT TESTS IN THE MERCANTILE MARINE.

THE Board of Trade has published the annual return of the sight tests used in the mercantile marine for the year ending December 31, 1910 (Parliamentary Paper, Cd. 5876), a return which includes the examinations in both form and colour vision. In the course of the year 7502 candidates were examined, including fishermen who sought to obtain certificates as skipper or second hand of fishing boats, and of this total 109 (1·46 per cent.) failed in form vision, and one of them, who was re-examined, failed again. One hundred and forty-one failed in colour vision, but of these 69 were re-examined on appeal, and 29 of them passed, leaving 112 (1·56 per cent.) as ultimate failures.

The colour examination, since November, 1909, has been conducted with five skeins of wool, a purple and

a yellow, in addition to the green, pink, and red originally used by Holmgren; and a coloured plate gives the colours which were selected as matches by the rejected candidates, and are distinguished by letters of reference in a schedule showing the performances of all the candidates who were ultimately rejected, and are therein described as completely or incompletely red or green blind. This information, however, is withheld in the very cases in which it is most required, that is, in the cases of candidates who, having originally been rejected, were passed on appeal. With regard to these, we are only told that they "failed in the colour vision tests," and, in another column, that they "appealed and passed." It would be highly interesting to know both on what grounds they were originally rejected and on what grounds they were ultimately passed, because these are the very cases in which the sufficiency of the methods of examination employed may possibly be called in question at some future time. The matter is perhaps of less importance, as we read in the report that "the whole question of sight tests is now being carefully considered by a Departmental Committee appointed for the purpose," and it is therefore possible that changes both of procedure and of record may be suggested.

Of the 112 men rejected for defective colour vision, 42 were completely and 21 incompletely green blind, and 32 were completely and 17 incompletely red blind, no instances of the rarer varieties of failure being recorded. The rejections are somewhat in excess of those of many previous years, and the explanation seems to be that the fishermen seeking certificates, as mentioned above, have only been required to pass the same sight tests as candidates for certificates as masters or mates in the mercantile marine since November, 1909, and that they have increased the proportion of defectives. As compared with the amount of defective colour-sense in the population generally, the proportion of rejections does not seem large, and it is highly probable that many colour-blind persons are prevented, by a knowledge of their condition, from attempting to enter the sea service.

WIND IN THE ADRIATIC AND IN HOLLAND.[1]

THERE has been in recent years a re-awakened interest in the problem of the periodic variations of the wind, but there remains much to be done to complete that thorough harmonic analysis of the motion of the air which Kelvin emphasised as one of the most important lines of meteorological research so long ago as 1876. Hitherto attention has been devoted mainly to a consideration of the semi-diurnal variation, and the results have shown conclusively that the regular semi-diurnal wave of pressure can, as indeed it must, be connected through the hydrodynamical equations with a similar regular variation of the wind-vector. In the discussion of the record for individual places, the question of the local variations from the general law and their explanation rightly find a place, but they ought not to be allowed to exclude the consideration of other possible periods.

In the first chapter before us, Dr. Mazelle, Director of the Observatory at Trieste, analyses five years' records from the Beckley anemograph erected in 1902 on a lighthouse in the Adriatic, the Klipper Porer, which lies a mile and a half W.S.W. of Cape Promontore, the most southerly point of Istria. The results have been very fully discussed, and the records are arranged and tabulated in many different ways to exhibit the different features inherent in them. A table giving the frequency of the wind for sixteen directions for the four seasons of the year shows that at all times the E.N.E. wind is most frequent, and that all easterly winds have their maximum frequency in winter and spring, while westerly winds are more frequent in summer and autumn. Another table, giving the diurnal variation of the frequency of the wind for the eight principal directions, shows that N.E. winds are most frequent about 3 a.m., and W. winds about 3 p.m., a result which may arise from land and sea breezes.

Diagrams are drawn to show the diurnal variation of the wind-vector for the four seasons and for the whole year. In general the vector rotates in a clockwise direction in the course of the day, but in winter the curve is looped and the rotation is counter-clockwise from 3 p.m. to 3 a.m. The variation is greatest during summer, and is greater in spring than in autumn. It would have been an advantage if the results had been analysed for the four principal directions, instead of for N.E., S.E., N.W., S.W., in order to permit of direct comparison with results from other places and with theory.

A considerable part of the paper is devoted to a discussion of strong winds or gales, especially gales from the N.E. quadrant, Bora, and from the S.E. quadrant, Scirocco. Dr. Mazelle takes a stormy day to be one on which the mean velocity of the wind is at least 50 kilometres per hour. There were 149 such days in the five years, or, roughly, one day in twelve. January had 33 such days, or rather more than one in five. June, on the other hand, had only one such day in the whole period. A curious and suggestive peculiarity is the secondary maximum in October, which had 18 stormy days, compared with 11 in September and November. The diurnal variation on a stormy day is about the same in summer as in winter, the maximum occurring at or slightly before noon in both seasons. For days of stormy Bora and Scirocco the definition is extended to include days on which the maximum velocity exceeded 50 kilometres per hour. There were 233 days of stormy Bora and 71 of Scirocco during the five years, a result which does not altogether support Horace's description of Scirocco or Notus as "arbiter Hadriae," "that tumultuous ruler of the restless Adriatic." Bora is most frequent in winter, the worst month being January, with an average of eight days; Scirocco is most frequent in autumn, with a maximum monthly average of 2·6 days in October. In every month the average number of days of Bora is greater than that of Scirocco.

Perhaps the best idea of the character of Bora and Scirocco is given by tables showing the length of the periods during which the mean velocity exceeded 50 kilometres per hour, and of periods during which the velocity never fell below 50 kilometres per hour. It is seen from these that on one occasion of Bora the wind blew uninterruptedly with a velocity exceeding 50 kilometres per hour for 144 hours, and that on the same occasion the mean velocity did not fall below 50 kilometres per hour for 7 days. The corresponding maximum periods of duration for Scirocco are 36 hours and 3 days. The absolute maximum velocity recorded during the five years was 128 kilometres per hour for Bora, 102 for Scirocco, 98 for S.W. gales, and 80 for N.W. gales. Unfortunately, the factor of reduction is not stated, so that it is not possible to compare these values with records for this country.

The second paper is a discussion contributed by

[1] "Die tägliche Periode der Windrichtung und Windstärke nach den anemometrischen Aufzeichnungen auf der Klippe Porer." By E. Mazelle. Besonders Abgedruckt aus dem lxxxvii. Bande der Denkschriften der Mathematisch-Naturwissenschaftlichen Klasse der Kaiserlichen Akademie der Wissenschaften. Pp. 65. (Wien: Alfred Hölder, 1911.)

"On the Diurnal Variation of the Wind and the Atmospheric Pressure and their Relation to the Variation of the Gradient." By Dr. J. P. van der Stok. Pp. 14. Koninklijke Akademie van Wetenschappen te Amsterdam. Reprinted from Proceedings of the Meeting of May 27, 1911.

Dr. J. P. van der Stok to the Proceedings of the Royal Academy at Amsterdam, "On the diurnal variation of the wind and the atmospheric pressure and their relation to the variation of the gradient." He criticises the method, adopted in previous investigations, of attempting to determine the variation of the wind from the variation of the gradient of pressure, and, regarding it as too laborious and affected with uncertain errors, attempts to determine the gradient from the observed variation of the wind. It would be interesting to institute a comparison between this method, that of utilising hourly observations of pressure at three stations, adopted by Tsuiji, and the general method based upon the regularity of the semi-diurnal wave of pressure.

Dr. van der Stok finds it convenient to assume that the semi-diurnal variation of the wind has the same phase angle as would be indicated by the theoretical application of the general method, and deduces the value of the coefficient of friction, *k*, which will ensure agreement between observation and theory in this respect. He then utilises this value of the coefficient to deduce the diurnal variation of the gradient of pressure from the observed diurnal variation of the wind. It seems desirable to consider in this application the difference, emphasised in a recent paper by Sandström, between friction due to motion over the rough surface of the earth and sea and the frictional effect which arises from the difference in direction and velocity between the wind at the surface and that at some distance above it. The results used in the investigation are the hourly observations, presumably estimates and not instrumental records, at de Bilt for five years 1903–1908, and the four-hourly observations at the Terschellingerbank Lightship for 25 years 1884–1908. The values found for *k* show a general agreement with those found by van Everdingen from the incurvature of the wind at de Bilt, but the value for Terschellingerbank is 50 per cent. larger. The coefficient shows a regular annual variation, with the maximum during autumn and winter, the minimum during spring and summer, an interesting result which ought to be compared with the values for inland stations. The author criticises the results of the analysis at St. Helena, on the ground that the wind-vector turns in a clockwise instead of in a counter-clockwise direction, but a reference to Dines's discussion of these results shows that, except for certain small irregularities in the night, the vector rotates in a counter-clockwise direction throughout the year. The vector of the variation of the horizontal magnetic force at St. Helena rotates in a clockwise direction except in July.

E. GOLD.

REPORT OF THE GOVERNMENT CHEMIST.

IN his report upon the work of the Government Laboratory for the year ended March 31, 1911, the principal chemist notes that the laboratory has now been constituted a distinct establishment under the Treasury. This is certainly a more appropriate arrangement than the previous one, under which the control was vested in the revenue authorities, for since the laboratory now serves many other State departments besides the fiscal ones, the control in question had become somewhat of an anachronism.

Last year the total number of samples dealt with was 186,044, as compared with 170,033 in the preceding year. The report describes the nature of these, with explanatory notes and statistics. As usual, they included the most diverse kinds of articles, from "standard" bread to poisoned salmon. From among the items of more or less general interest mentioned in the report we extract the following.

Beer and brewing materials are regularly tested for the presence of arsenic, and 41 out of 638 samples were found to contain arsenic in excess of the prescribed limit. Steps were taken in these cases to prevent the contaminated article being sent into consumption, and to trace the source of the arsenic. Usually this was found in the fuel used for drying the malt.

Two interesting cases of fish-poisoning are noted. In one instance dead trout were found (Kensey Brook, Tamar and Plym District), and analysis of the water showed that the brook had been contaminated with ammonia from a gas works. In the other case, dead salmon had been found in the Conway district, and as there are lead mines near it was thought that the fish might have been poisoned by drainage containing lead. On analysis, however, zinc, and not lead, was discovered in the salmon, as also in the river water; this served to indicate the source of the pollution and explain the destruction of the fish.

One curious question referred to the laboratory was whether the composition of a particular clay was such as to distinguish it from the exempted "common clay" of the Finance Act of 1909–10; the report is silent as to the conclusion arrived at. Questions connected with the pigments, paper, and gum used in making postage and other fiscal stamps were also investigated. At the house of a coiner, it is stated, a plate and apparatus were found, all ready for the production of illegal stamps. "His productions were somewhat crude," the principal chemist remarks; "but were sufficiently good to deceive an unobservant person, especially in a poor light."

In connection with dangerous trades a number of pottery glazes were examined. They included a series of forty-eight taken from works where lead-poisoning had occurred, and it is a significant fact that except in two or three cases, practically the whole of the lead in these samples was "soluble" lead. Large proportions of lead were also found in dust collected from various factories, other than potteries.

Space allows mention of only one more of the many interesting matters to be found in the report. A question arose respecting the authenticity of a portion of an "Account Book of Revels" of the years 1604–5, preserved in the Public Record Office. This document is a manuscript containing details of expenses incurred in producing certain plays, including *Othello*, respecting the production of which at so early a date there has been much controversy. Suspicion had been cast upon the manuscript, the suggestion being that the entries in question had been made about forty years ago, just before the book had passed into the custody of the Record Office. "After a searching microscopical and chemical examination of the ink and paper in different parts of the document," the principal chemist was able to report that in the character of the ink, the depth to which it had penetrated, or the degree of fading, there was no evidence whatever of any difference between the impugned writing and that in other parts of the document.

C. S.

PRINCE BONAPARTE'S AIDS TO SCIENTIFIC WORK.

THE announcement of the gift of 250,000 francs to the Paris Academy of Sciences by Prince Roland Bonaparte has already been made in these columns. The issue of the *Comptes rendus* of the Academy for November 27 includes a copy of the letter from Prince Bonaparte to the president of the Academy, M. Armand Gautier, announcing his intention, and also the remarks of the president after reading this letter to the meeting of the Academy. A free translation of both is subjoined.

In accordance with a feeling expressed many times, I have arrived at the conclusion that it is not by the institution of new prizes with the conditions of award fixed beforehand that the cause of scientific progress can be served most effectively. Undoubtedly it is an excellent thing to reward good work, but it is of greater importance to encourage the growth of original investigation by removing those obstacles which are apt to paralyse the peace of mind of men engaged in research work, of which the principal is generally the question of ways and means.

Impelled by this idea, I created in 1908 the Fonds Bonaparte. Anxious to continue this work, I am placing at the disposal of the academy a further sum of 250,000 francs, not as a capital sum, but in the form of five annuities, intended to be used at once in the spirit I have indicated; that is to say, putting aside all idea of recompense for work accomplished already, whatever its merit may be, my wish is that this sum may be used to stimulate discoveries by rendering easier the researches of workers in science who, having already given proof of their ability to undertake original work, and not belonging to our academy, lack sufficient resources to undertake or to follow out their investigations.

I therefore ask the academy to allocate in 1912, 1913, 1914, 1915, and 1916 these new annuities in the same manner that it has already, in previous years, dealt with the earlier annuities of the Fonds Bonaparte.

Devoted as I am to all scientific studies, I shall be happy, and my object will be gained, if I can in this way help to increase the amount of positive knowledge.

The president said:—

I do not think I need ask the academy to give its approval to this further liberality that Prince Roland Bonaparte offers us to-day. The academy accepts the gift with gratitude.

Not satisfied with continuing to help, as he has done for the last four years, young men of science who might have been stopped in their researches by material difficulties, our colleague doubles the amount which he places at their disposal by making it 50,000 francs a year for five more years. The number and value of the researches which his gifts have made possible during the four years which are almost at an end lead us to hope that the results will be still better for the new period which begins in 1912.

With its president, the academy and French science thank Prince Roland Bonaparte very heartily for his generosity and invaluable initiative.

NOTES.

We notice with deep regret the announcement of the death, on Sunday, December 10, at ninety-four years of age, of Sir Joseph D. Hooker, O.M., F.R.S. In the scientific world he occupied a place in the front rank, and his name and work will be permanently prominent in the history of scientific progress in modern times. Thirty-four years ago, on October 25, 1877, an appreciative article on his services to science was contributed to our columns by Prof. Asa Gray in the eleventh article of our series of Scientific Worthies. We need only refer to that article now as an indication of the high esteem in which Sir Joseph's unusual gifts and energies have long been held by those most competent to estimate their value. We hope in our next issue to supplement this article with another, and here only remark that his botanical knowledge was unrivalled, and his work has won the gratitude of the whole civilised world. The announcement was made on Tuesday that the Dean of Westminster had, with the full concurrence of the Chapter, offered to the family to permit the interment of Sir Joseph Hooker's ashes in the Abbey, on the condition that his remains were previously cremated. It would have been appropriate for his remains to rest in the north aisle of Westminster Abbey among those of Newton, Sir John Herschel, Darwin, and Kelvin, and near the memorials of Adams, Stokes, and Joule. The family has, however, felt obliged to decline the offer of burial in the Abbey, as it was Sir Joseph's express wish that he should be buried by the side of his father at Kew. The funeral will therefore take place at Kew Parish Church to-morrow (Friday) at two o'clock. It is specially requested that no flowers be sent.

The list of honours conferred by the King on the occasion of his Majesty's visit to India, and in commemoration of the Coronation, is published in a supplement to *The London Gazette* of December 8. Among the names in the list are those of several people concerned with scientific work. We notice the following in a long list of appointments and promotions:—*K.C.S.I.:* Surgeon-General C. P. Lukis, Director-General, Indian Medical Service. *C.S.I.:* Colonel S. G. Burrard, F.R.S., Officiating Surveyor-General of India; Mr. F. B. Bryant, Inspector-General of Forests to the Government of India; Dr. G. T. Walker, F.R.S., Director-General of Indian Observatories; Prof. J. C. Bose, Presidency College, Calcutta. *K.C.I.E.:* Mr. Eardley-Wilmot, lately Inspector-General of Forests to the Government of India. *C.I.E.:* Major Leonard Rogers, professor of pathology, Medical College, Calcutta, and bacteriologist to the Government of India; Mr. H. H. Hayden, Director of the Geological Survey of India. *Knights Bachelor:* Mr. R. P. Ashton, president of the Mining and Geological Institute, Calcutta; Lieut.-Colonel C. H. Bedford, Chemical Examiner, Bengal.

The Nobel prizes were distributed by the King of Sweden on December 10. Three of the prize-winners—Mme. Curie (chemistry), Prof. W. Wien (physics), and Prof. A. Gullstrand (medicine)—were present personally to receive their prizes.

We regret to announce the death, on December 11, after a very short illness, of Mr. William Thynne Lynn. The son of a physician in Westminster Hospital, he was born at Chelsea in 1835. He was for a short time assistant in the Cambridge Observatory, and was assistant at the Royal Observatory, Greenwich, from 1856 to 1880, when he retired from official duties. He was elected a fellow of the Royal Astronomical Society in 1862, and contributed several papers to the Monthly Notices. In 1900 he became a member of the British Astronomical Association, was the author of many papers in its Journal, and was a member of the council at the time of his death. He was associated with Prof. D. P. Todd in the authorship of "Stars and Telescopes," and, among other works, wrote the popular little treatises "Celestial Motions," "Remarkable Comets," and "Remarkable Eclipses," each of which ran through several editions. He was a constant contributor to *The Athenaeum*, *Observatory*, and other journals, principally on subjects connected with the history of astronomy and the calendar, and occasionally contributed to our pages. His knowledge of astronomy generally, and especially of its history, was unusually extensive. On subjects connected with chronology he was also extremely well informed, and was always ready to place his knowledge at the service of others.

We regret to learn of the death of Mr. H. Snowden Ward, which took place in New York about a week ago, after an exceedingly short illness. Mr. Snowden Ward was a journalist and publisher who was well known in this country as being energetically interested in all branches of photography, but especially in the progress of methods of photomechanical reproduction, and, later, in the advance of pictorial photography. His endeavour to get the word photograph, when used as a substantive, replaced by "photogram," which he maintained was more correct, was always kept to the front by the name of his monthly

journal *The Photogram* and his annual "Photograms of the Year." Of late years Mr. Snowden Ward, while continuing his journalistic work, studied the life and writings of Charles Dickens, with special reference to the actual places and circumstances referred to by the novelist. He was giving lectures on this subject in the United States when he was taken ill. He was only forty-six years of age.

THE death is announced, at fifty-two years of age, of Dr. E. F. Trevelyan, formerly professor of therapeutics at the University of Leeds, and professor of pathology at the Yorkshire College, then a constituent of the Victoria University.

PROF. G. ELLIOT SMITH, F.R.S., professor of anatomy in the University of Manchester, has been awarded by the Paris Anthropological Society the Prix Fauvelle, of one thousand francs, for his researches in the anatomy and physiology of the nervous system.

PROF. F. B. LOOMIS, who left Amherst College, Mass., in July at the head of an exploring expedition to Patagonia, has written to a colleague an outline of his progress up to the beginning of October. He had not been able to secure many fossils, but could already see that the expedition would be able to revise the geology of the country traversed. Many of the beds previously described as land deposits were, in his judgment, marine.

THE death is announced, on December 5 at Gloucester, in his seventy-eighth year, of Dr. Francis T. Bond, for thirty-eight years medical officer to the Gloucestershire combined sanitary district. Dr. Bond was formerly professor of clinical medicine at Queen's Hospital, Birmingham. From 1862 to 1873 he was principal of the Hartley Institute, Southampton. He translated Radicke's work on "Medical Statistics," and was a frequent contributor to medical and sanitary journals. Dr. Bond was an early worker in bacteriological research and was interested in scientific agriculture; he elaborated a method of cheese manufacture, and invented a filter and other hygienic devices.

THE presentation of the testimonial to Mr. Henry Keeping on his retirement from the post of curator of the Geological Museum, Cambridge, took place in the Sedgwick Museum on Saturday, December 2, when Prof. T. McKenny Hughes handed him a purse subscribed by old friends and students in recognition of his long and valuable services. Mr. Keeping entered upon his duties as curator fifty years ago under Prof. Sedgwick in the old Woodwardian Museum, where the geological department was located until its removal into the Sedgwick Museum in 1904. In collecting fossils in the field Mr. Keeping has displayed exceptional ability and skill; and amongst the mass of specimens which he has thus added to the museum special mention should be made of the remarkably rich series of Tertiary fossils from the Hampshire basin which his keen eye and intimate knowledge of the beds of that area have enabled him to obtain.

AN interesting discovery is reported from Western Canada. During the summer Mr. Andrew Gordon French discovered what is claimed to be one of the largest mines of reef platinum metals in the world in the dyke rocks of the Nelson district, British Columbia. He has now announced the discovery therein of a new element, to which he has given the name Canadium. The element is described as a new member of the family of noble metals, with a melting point somewhat lower than that of silver and gold, possessing a brilliant white lustre, easily soluble in hydrochloric and in nitric acids, not tarnished by damp air, sulphuretted hydrogen, alkaline sulphides, or tincture of iodine, and not precipitated from its solutions by chlorides or iodides. Continued heating in the oxidising flame does not oxidise the molten metal, though some specimens, when first heated, give off dense fumes, which may be due to osmium, or possibly to something also new. It is electronegative to silver, is precipitated from its solutions by zinc, and, when alloyed with lead, may be separated by cupellation. The metal occurs pure as semicrystalline grains, and in short rods about 0·5 mm. long and 0·1 mm. thick, and also alloyed with the other platinum metals. Quantities up to 3 oz. per ton have been found in the rock. It is more brilliant and lustrous than palladium, and softer than platinum, ruthenium, and osmium. The new metal is thus well characterised and clearly differentiated in properties from all known substances, and the confirmation of the discovery will be awaited with interest. Mr. French has had wide practical experience in the extraction and separation of the platinum metals with various bullion-smelting firms in this country, and is a native of Glasgow.

MR. J. C. ROBERTSON, of 119 Victoria Road, Kirkcaldy, has sent us a communication relating to recent proposals for the reform of the calendar. For the most part his remarks add little to the information conveyed in our articles of April 27 and October 26. But he also takes occasion to advocate the setting back of the year by ten days in order that its beginning may coincide with the winter solstice. This suggestion cannot be supported on the ground of any advantage in commercial affairs, and the chief interest which it has for us lies in the light which it throws on the mental attitude of the prominent reformers. In criticism of the provisions of the Fixed Calendar Bill, we suggested the case of a servant engaged on March 32, and wished to know the date of the first monthly payment and the rule for calculating its amount. On the first point Mr. Robertson confirms our surmise that the due date is April 28. This, it may be observed, implies that in practice a month may be any period from twenty-eight to thirty-five days—a truly great improvement on our present system! He then suggests that the payment will be by special agreement one-twelfth of the annual wage. But again it is difficult to appreciate the simplicity of a calendar which needs to be supplemented by special agreements. Alternatively, he states that the Bill provides that the payment shall be in proportion to the length of service. We believe that according to the Bill payment should be in proportion to the number of weeks in the month. When, as in the case suggested, a fraction of a week is involved, we were at a loss for a rule, and Mr. Robertson has not convinced us that the Bill is explicit on the point. We have no wish to press this simple example too far, but we do think that the reformers have altogether underrated the practical difficulties of the problem and undervalued the legitimate objections which can be brought against their solution of it.

MR. HERON-ALLEN informs us that the violent gales at the end of November have enabled him to make two very remarkable finds at Selsey, near Chichester. One is a series of Proteoliths in the seldom exposed Pleistocene mud bed on the west coast, which Sir Ray Lankester pronounces to be of the rostro-carinate eagles's-beak form, similar in shape and date to the sub-Crag Proteoliths of which frequent mention has been made in these pages. Mr Heron-Allen is handing them all over, together with the Selsey Palæoliths and Mesoliths, to Sir Ray Lankester,

who is at work on this subject. The other "find" is a British gold stater, dished and plain on one side, and bearing on the other the impress of a die not to be found in Willett's or Evans's works, and which, until Mr. Heron-Allen deposited his coin at the British Museum, was unknown and unrepresented in the national collection.

In describing (*Archaeologia Æliana*, ser. 3, vol. vii.) the animal remains obtained during the excavations on the site of the Roman city of Corstopitum, near Newcastle-upon-Tyne, in 1910, Messrs. A. Meek and R. A. H. Gray state that the bones and skulls of many of the oxen agree very closely with those of the white cattle of Chillingham and other British parks. A peculiarity said to characterise both is the absence or early shedding of the antepenultimate lower premolar. On this ground both the Chillingham and the Roman cattle are declared to represent a new wild species, for which the name *Bos sylvestris* is proposed; but whether this is typified by the former or the latter the reader is left to decide for himself. They ignore the fact that park-cattle already possess a scientific name —*Urus scoticus* of Hamilton Smith—and likewise that the colour of these cattle is decisive as to their domesticated origin. Most naturalists would likewise regard the alleged absence of the anterior premolar as a feature due to domestication.

In a study of the Pacific Ocean in its relation to ethnography, contributed by Dr. J. M. Brown, regent of the University of New Zealand, to part i., vol. ii., of *The Journal of Race Development*, the writer lays special stress on the region of subsidence. This he believes to account for one of the most singular phenomena in human culture. "These central groups are occupied by a people, the Polynesians, who in some of their arts, the masculine, those of war, navigation, architecture, and carving, rise to the highest levels of the barbaric stage. And yet they have adhered to arts that are purely Palæolithic: these are the art of thread-making, that of fire-making, and the fictile art; they have never had a spindle: they have a pump-drill, but they have never applied it to the production of fire; and though they have plenty of clay, they have never made pottery. In early stages of culture these belong to the women's department, and woman, guided as she is by emotion oftener than by reason, is more conservative than man. This Palæolithic element in the household culture seems to indicate that man has been in Polynesia since Palæolithic times, and that woman came into those regions only in those times, when there were still only short canoe voyages to make to land that could be seen on the horizon."

Nos. 46 and 47 of the Scientific Memoirs of the Government of India deal respectively with "Malaria in the Punjab," by Major Christophers, and "Dysentery and Liver Abscess in Bombay," by Major Greig and Captain Wells. Malaria in the Punjab is manifested in two ways, as "endemic malaria" and as "autumnal epidemic or fulminant malaria," the latter—the more important—being associated with a high mortality. The determining causes of epidemics are excessive rainfall and scarcity, though the epidemic areas are not necessarily coincident with those of heaviest rainfall. The determining factor of epidemic and fulminant malaria is found to be flooding, and the villages are attacked almost exactly in proportion as they have been flooded. Experiments with sparrows and the Proteosoma, a parasite analogous to the malaria parasite of man, and similarly conveyed by mosquitoes, show that severity of infection is largely dependent on the dose inoculated, and the latter depends not merely on the number of mosquitoes biting, but on the number of sporozoites injected at each bite, and this, again, depends on the richness in parasites of the blood of the individual from whom the mosquito derives the infection. The memoir contains a number of plans and illustrative charts. As regards Memoir 47, on dysentery, though bacillary dysentery occurs in Bombay, it is infrequent, and the form associated with amœbæ is more prevalent. The prevalence of amœbæ shows a marked seasonal variation, which follows the humidity, and not the temperature, curve in Bombay. The amœbæ can be cultivated, and are not *Ent. histolytica* or *coli*, but are probably the same form as that observed by Noc in Cochin China. Apparently the same amœbæ can be cultivated from tap water in the districts, and the evidence at present available indicates that water is probably the channel by which this form of dysentery is disseminated.

To vol. iv., part iii., of the Transactions of the Hull Scientific and Field Naturalists' Club, Mr. T. Sheppard contributes notes on the post-glacial, glacial, and pre-glacial faunas of East Yorkshire. The glacial beds have yielded remains of mammoth, straight-tusked elephant, elk, reindeer, red deer, Pleistocene bison, aurochs, rhinoceros, and walrus.

The question of the nature of the diet of the extinct giant phalanger (*Thylacoleo carnifex*) has been incidentally revived by Messrs. Baldwin Spencer and R. H. Walcott in a discussion as to the origin of cuts on bones of extinct Australian marsupials (Proc. R. Soc. Victoria, vol. xxiv., pp. 92–123). Such incised bones occur at considerable depths—sometimes beneath beds of tufa—and the authors consider that the cuts were probably made by the teeth of Thylacoleo. The name given to the giant phalanger by Owen indicated his opinion as to its carnivorous habits; but this view was disputed in 1868 by Sir W. H. Flower, who thought that its diet was probably vegetarian, although it might have included flesh. Thirty years later Dr. R. Broom argued that Owen was right; and if Messrs. Spencer and Walcott are correct in their view as to the origin of the aforesaid cuts, the carnivorous habits of the giant phalanger are definitely proved.

In the volume on mammals in the "Fauna of British India," the late Dr. W. T. Blanford stated that the black-buck (*Antilope cervicapra*) living on a spit of sand between the Chilka Salt Lake, in Orissa, and the sea, never drank, as there is no water on the spit except in deep wells. The statement has been strongly controverted by various writers, one at least of whom has suggested that the antelopes obtain water from sheep-troughs. Of late years it has, however, been conclusively shown that giraffes, kudu, and gemsbok live for a considerable portion of the year in the Kalahari Desert without drinking, obtaining such moisture as they require from the succulent roots of certain plants. In a letter published in *The Field* of November 25 Dr. Drake-Brockman records a very similar instance in the case of the maritime gazelle (*Gazella pelzelni*) in Somaliland. In July, 1910, five of these gazelles were placed on the island of Saad-ud-din, which is absolutely waterless save on the rare occasions when showers fall. There is, however, a succulent Schweinfurthia, of which the gazelles are fond, and a lily with a large onion-like root, which is scraped out of the sand and eaten by the gazelles. These are absolutely the only sources of moisture obtainable by the antelopes, which have now lived on the island for about eighteen months, since it has been clearly proved, by the absence of their tracks from the shore, that they do not drink sea water. The case of the Chilka black-

buck accordingly requires reinvestigation in order to ascertain whether they too may be able to obtain moisture from plants.

THE sponge fauna of the Kola-Fjord forms the subject of a paper (with a summary in German) by Mr. L. L. Breitfuss in *Trav. (Comptes rendus) Soc. Imp. Nat. St. Petersbourg*, vol. xlii., part i. In the second fasciculus of the same part Dr. Weltner describes (as the seventh instalment of the account of the fauna of Turkestan) the sponges of the Issyk Kul (Lake Issyk) and the neighbouring rivers of the district north of the Tian Shan. These belong to the almost cosmopolitan *Ephydatia fluviatilis*, and from the fact of its occurrence in the Issyk Kul, which is about 5300 feet above sea-level, at a depth of as much as 40 metres, the species is regarded by the author as a member of the high-mountain and deep-lake fauna. At depths between 15 and 30 metres there was found from the middle of July to the end of August a form which produces sexual buds. Since, however, only a few unripe gemmules with misformed amphidiscs were then found, it is considered that the development of normal sexual gemmules must occur at some other season.

A CATALOGUE of the periodicals, Transactions of societies, and similar publications contained in the library of the Royal Botanic Garden, Edinburgh, has been compiled and published as Nos. xxvi. and xxvii. of "Notes" from the garden. With a view to the utilisation of the separate items as index slips for public or private use, the printing is limited to one side of the page.

A CONTINUATION of garden notes on new trees and shrubs, prepared by Mr. W. J. Bean, appears in *The Kew Bulletin* (No. 8). Chinese introductions include a distinct rough-stemmed bush, *Berberis verruculosa*; a beautiful hornbean, *Carpinus polyneura*; and the new conifer, *Fokienia Hodginsii*. Another interesting and rare Chinese conifer, represented at Kew by several specimens, is the lace-bark pine, *Pinus Bungeana*; a peculiarity of this tree is the white bark, but it is noted that this is a very late development, and has not yet been attained by the Kew specimens. Noteworthy, also, is the small American tree *Leitneria floridana* that by itself constitutes the family Leitneriaceæ; the wood produced is perhaps the lightest known, having a specific gravity about 0·2.

THE original homes of our cultivated plants is a matter of considerable interest to gardeners, so that Mr. A. W. Hill found an appropriate subject in the relation of South America to horticulture for a lecture before the members of the Royal Horticultural Society, that is published in the Journal (vol. xxxvii., part i.). The "monkey puzzle," *Araucaria imbricata*, emanates from Chile, and from that State or Peru have come many hardy or half-hardy shrubs, including *Berberis Darwinii*, *Azara macrophylla*, and *Drimys Winteri*. Less hardy, and therefore requiring greenhouse cultivation, are the climbers Stigmaphyllon and Tacsonia, and the wall plants *Streptosolen Jamesoni* and *Lapageria rosea*. Species of Begonia from South America have contributed materially to the development of modern garden varieties, while no less interesting are the species of Calceolaria and Fuchsia that are strongly represented on that continent, and several brilliant species of Tropæolum.

PROF. D. H CAMPBELL is well known to botanists as the author of many valuable and important memoirs on the morphology of vascular cryptogams. A recent number (No. 140) of the Publications of the Carnegie Institution of Washington embodies a connected account of the eusporangiate ferns, in which he has brought together in a very complete form the result of his researches on the comparative morphology of the Ophioglossaceæ and Marattiaceæ. The memoir, which contains 224 pages of text, and is amply illustrated by text figures and plates, is fully worthy of the high reputation of Prof. Campbell, and it will be indispensable to all students of this interesting group of plants. After an extensive account of the structure and development of a considerable number of species the author draws certain general conclusions as to the phylogenetic significance of the structures he describes. Thus, as a result of a discussion of the evolution of the vascular structure, he regards the vascular system of the stem of, *e.g.*, Marattiaceæ as a collocation of leaf bundles, and discards the "stelar" view, as it is generally held, on the ground that it obscures a right interpretation of the facts. As might have been anticipated, the author deals with the supposed origin of the eusporangiate ferns (which he regards as a primitive group) from a bryophyte stock, and the analogies and comparisons he draws between the embryo of species of Ophioglossum and of Anthoceros are striking. Naturally he does not suggest a derivation of the ferns from Anthoceros as it now exists, but he points out very cogently the remarkable features of resemblance that actually exist. All who are interested in the evidence on which the speculations respecting the ancestry of the higher plants are founded will find matter of great interest in Prof. Campbell's memoir, whilst as a repository of facts which, whatever be the fate of theories and hypotheses, will always retain their face values, the memoir forms a considerable contribution to the permanent literature of botany.

THAT branch of the United States Department of Agriculture concerned with the introduction of foreign seeds and plants has achieved success largely owing to the systematised methods of procedure and the activities of the explorers in charge. One of the latter, Mr. D. G. Fairchild, contributes to *The National Geographic Magazine* (October) a popular illustrated article in which a few of the important introductions are noted. Probably the greatest undertaking has been the importation of date-palm suckers, which have been planted in the States of Arizona and California. From India, mangoes have been imported in large variety, and are being grown in Florida, Porto Rico, and Hawaii. The production of Oriental persimmons and the cultivation of bamboos on a commercial scale are also notable enterprises, as well as the introduction of a new vegetable, "udo," *Aralia cordata*, from Japan, comparable to and said to rival asparagus.

THE report on the permanent experiment field of the Roseworthy Agricultural College, published in *The Journal of the Department of Agriculture of South Australia*, contains some very interesting results. Perhaps the most remarkable is the great increase in the wheat crop obtained by applying small dressings of superphosphates, the grain rising from twenty-one to twenty-six bushels, and the straw also showing a marked increase. Nitrate of soda did not produce anything like the effect that would be looked for in this country, a result probably to be attributed to the lack of moisture, which would operate as a limiting factor. In the same Journal it is also stated that the broom millet (*Sorghum vulgare*, var. *technicum*) can be grown profitably in certain parts of the State. Stress is rightly laid on the value of any new crop likely to widen the basis of the local agriculture. Mention is also made of the fact that varieties of wheat which have proved admirably suited to Australia were wholly unsatisfactory in Great Britain

THE third volume of results published by the Geological and Natural History Survey of Connecticut contains three bulletins, "The Lithology of Connecticut," by Prof. Barrell and Mr. G. F. Loughlin; "Catalogue of Flowering Plants and Ferns of Connecticut Growing without Cultivation," by the Committee of the Connecticut Botanical Society; and "Second Report on the Hymeniales of Connecticut," by Prof. E. A. White. One object of the Survey's publications is to enlist the interest of the general community, in which connection Prof. Barrell's "Introduction to Lithology" is noteworthy for its luminous thoroughness. The economic value of all soils is carefully investigated by Mr. Loughlin. On the same principle, the useful or deleterious properties of flowering plants and fungi receive full notice. Prof. White has made considerable experiments with mushrooms, and the number of edible and wholesome Agaricaceæ is surprisingly large. His descriptions of fungi, illustrated by some excellent photographs, are very complete. The catalogue of flowering plants and ferns comprises 2228 species; nothing that has not been authenticated is included. Distribution is uneven; Connecticut soils, being formed from transported material, often differ from the underlying rock. In the south-eastern portion of the State there is a small group belonging to the flora of the Atlantic coast plain of the middle and southern States, probably a remnant of a larger colony. Among interesting species are the dwarf mistletoe, parasitic on the black spruce; and the numerous representatives of Rhododendron and Cypripedium. In 1907 an Act of the General Assembly was put into force, by which "The Mountain Laurel, *Kalmia latifolia*, is hereby made, constituted, and declared to be the State Flower of the State of Connecticut." The prevailing difficulties of nomenclature are well illustrated in this careful list. It will, in connection with the full geological knowledge of the State, enable some investigations to be made of considerable ecological interest.

HEFT 3 of the current volume of the *Mitteilungen aus den Deutschen Schutzgebieten* is mainly devoted to the final portion of an account of the Cameroon Mountains, by Dr. K. Hassert. The hydrography is fully treated, and the distribution of water, with its remarkable inequality, is brought out. The coastal slopes have as high a rainfall as any part of the earth's surface, while the south-eastern, eastern, and northern regions are but imperfectly supplied. The fauna and vegetation are shortly described, and the inhabitants are discussed. A section on the economic products of the region, and two appendices dealing with the observations of altitude and the determination of geological specimens complete the article.

MR. V. N. LEBEDEF investigated the hydrology of the Kamchatka River in 1908–9, and has given a preliminary account in the *Isvestiya* of the Russ. Geogr. Soc., Nos. i.–v., 1911. The river is a mighty stream, being more voluminous in its lower course than the Dnieper, and discharging when low fully 42,380 cubic feet of water per second. A greater aggregate of low temperatures is required to bring it to the freezing point than any other river of Siberia, probably owing to the high temperature of the springs that feed it. It receives tribute also from the melting of the snow and ice in the mountains, while rain is of secondary importance. The lakes of eastern Kamchatka are in summer not colder than similar lakes in Europe, notwithstanding the great difference in climate, while in winter they are even warmer, because they are frozen over earlier. The stream that drains the Nerpichye Lake is, unlike most lake outlets, warmer than the air soon after the thawing of the ice. A map of the delta of the Kamchatka River with its numerous islands, channels, and creeks accompanies the article.

MR. I. KARK, who has studied the Murgab River in relation to a project for storing the surplus water in spring to be used for irrigation in summer has published the results in the *Isvestiya* of the Russ. Geogr. Soc., Nos. viii.–x., 1910. At Tashkepri the minimum discharge of the river in September is 1330 cubic feet a second, and the maximum, in March, 5608 cubic feet, while the annual flow of water is more than 694 thousand million cubic feet. The solid matter carried down by the stream, which silted up a reservoir constructed some years ago at Yolatan, is derived principally from the sand and clay of the loss deposits below Takhtabazar. Below Sultanbent and Yolatan, where the delta may be considered to begin, the load is deposited, and, raising the general level of the country, forces the river to seek a lower course westwards. Hence it is that the town of Merv has moved in the same direction. Mr. Kark suggests that borings should be executed to ascertain the practicability of obtaining water by artesian wells. These borings would also yield information regarding the depth of the solid rocks and their age.

THE meteorological chart of the North Atlantic Ocean for December, issued by the Deutsche Seewarte, gives some news received from the German Antarctic Expedition. The ship *Deutschland* left Buenos Ayres on October 7 for a position near latitude 48° S., longitude 30° W., in order to determine by soundings whether a shoal exists there, as surmised by several shipmasters. The vessel would then visit the South Sandwich Islands to explore the floor of the ocean in their vicinity, and afterwards repair to South Georgia to take in stores, &c., this month. From there it would take a direct south-east course to the neighbourhood of Coats' Land, and make the eastern part of Weddell Sea, where less pack-ice is likely to be found than in the south-western corner. If land is reached a station will be established, and the ship will endeavour to get free of the ice by March next. In the southern summer of 1912–13 it will return for the removal of the members of the expedition. Particulars of successful landing on the Antarctic shore may be looked for about April next.

IT is impossible to read the monthly issues of the Bulletin of the American Mathematical Society without realising that American mathematicians are a much more powerful and well-organised body than their fellow-workers in this country. In an article on "American Mathematics" in *The Popular Science Monthly*, Prof. G. A. Miller shows that much still remains to be done before America can occupy a position of equality with the leading mathematical centres of the world, and his remarks certainly appear to apply with even greater force to England. It may perhaps be rather doubted whether the imperfect definitions of such words as "matrix" or "algebra" given in ordinary dictionaries can be regarded as affording much conclusive evidence, since it is probable that similar defects might be found in their treatment of other branches of science; but Prof. Miller is on firmer ground when he directs attention to the absence of any popular encyclopædic works of general reference in the English language dealing with the developments and history of higher mathematics. "As the result of this lack of intermediate mathematical literature, comparatively few of our people know what constitutes a mathematician of high order."

THE Journal of the Washington Academy of Sciences for November 19 contains a short account of the results obtained by Messrs. Rosa, Dorsey, and Miller in a deter-

mination of the ampere in absolute measure at the Bureau of Standards. A current balance of the Rayleigh type was used, a coil being suspended from one pan of a balance so that it hung horizontally between two horizontal fixed coils of double its diameter, the three coils being coaxial. The change of weight in one pan of the balance necessary to maintain equilibrium when the current in the fixed coils was reversed was determined. The absolute value of the chemical equivalent of silver obtained by means of the balance is 1·11804 milligrams per coulomb. The value adopted at the London Conference in 1908 was 1·11800. The electromotive force of the Weston normal cell at 20° C., obtained by sending one absolute ampere through an international ohm, was found to be 1·01822 volts.

AT the recent Karlsruhe meeting of the Naturforscher-versammlung Prof. von Kowalski, of Freiburg (Switzerland), gave a summary of our present knowledge of the phosphorescence of organic substances at low temperatures, a knowledge which we owe largely to the observations made by him and his pupils. Many organic substances which exhibit no signs of phosphorescence at ordinary temperatures become phosphorescent in liquid air, and the intensity of the effect is increased if the substance is in solution in water or in alcohol to a concentration of about one-twentieth normal. Subjected to ultra-violet light for an instant, the solid solution gives a continuous phosphorescent spectrum, which gradually fades away, the longer waves disappearing first. If the exposure to the light is continued for a second or more the phosphorescent spectrum shows, in addition, a number of bright bands which persist longer than the continuous spectrum, and in fading away appear to spread themselves over the whole spectrum. These bands are intimately connected with the chemical structure and with the ordinary absorption spectrum of the substance investigated. Their positions can be obtained by displacing the absorption bands through a fixed interval towards the red end of the spectrum.

SEVERAL new models of microscopes, particularly the type known as the "Handle Model," are described in a catalogue received from Messrs. R. and J. Beck, Ltd. It is a matter of no small importance to the student to be able to lift his instrument without fear of straining any of its parts or of dislocating the objective in relation to the object. Many cheap microscopes are so designed that it is necessary when moving them to grasp the base; otherwise considerable strain is thrown on the fine adjustment. The models referred to are made in different patterns to suit either the student or the advanced worker, and in either case the price is moderate. The cheapest of the series is an example of what can be done in this country when modern methods of production are adopted. It is probably the least expensive microscope, for the adjustments provided, at present to be obtained of either English or Continental manufacture. The fine adjustment is of the lever type, so that the chance of it getting out of order or of becoming less accurate as the result of wear is reduced to a minimum. The stand is supported on a foot of the horseshoe type, and the objections to this design are to some extent obviated by lengthening the point of support towards the observer, with the result that increased stability is secured.

STUDENTS and teachers of applied mechanics in search of new examples as test exercises will find the set prepared by Mr. C. E. Inglis (Cambridge University Press, price 2s. 6d. net) to be of service. There are, in all, 100 exercises, divided into twenty papers; these are chiefly drawn from examination papers set at the Cambridge Engineering Laboratory, and the standard of most of the problems is that of the "A" papers in the Engineering Tripos examinations. Answers to the problems are included, but no hints for solution are given; hence the questions fulfil the purpose of the author, which is to provide material for the student who has learned many principles, but must also gain self-reliance in the application of the knowledge he has acquired. The problems given cover a wide range, and include exercises in structures, machines, strength of materials, and higher applied mechanics generally. The diagrams are well drawn and are clearly dimensioned. Many of the problems bear the stamp of novelty, and are suggestive of others on the same lines. Students preparing for the final engineering examinations of any of the universities should find the book useful.

Engineering for December 8 contains an account of a peat-gas plant which has been working at Portadown, in Ireland, since September last with results which are reported to be quite satisfactory. The plant works with air-dried peat, and consists of two producers of 200 brake-horse-power capacity each, together with coke-scrubber, tar-extractor, sawdust scrubber, exhauster, and expansion box. The peat is fed in block form into a hopper above the producer, whence it falls into the producer itself as combustion proceeds. The gas is drawn off through the coke-scrubber and washer to the tar-extractor, where the tar is extracted under centrifugal action. It then passes on to the sawdust scrubber, and is delivered to the gas-holder by a high-speed fan, which draws it through the plant. The heating value is about 140 British thermal units. This plant has replaced a Mond-gas plant by which power was formerly provided, and figures are given in comparison of the cost of the two methods of power-gas production. The net expense for fuel in the peat-gas plant is 4*l.* 5*s.* per week. The anthracite used in the Mond-gas plant cost 13*l.* 16*s.* 3*d.* per week. The plant has not been running sufficiently long to ascertain definitely whether a slight increase in labour may be necessary; but, allowing 40*l.* per annum for such a contingency, under these conditions at a factory of 500 looms, employing 500 to 600 hands, a saving in the fuel bill of about 438*l.* would result. The plant was constructed by Messrs. Crossley Brothers, Ltd., of Manchester.

A SECOND French edition of the first part of vol. i. of Prof. O. D. Chwolson's "Treatise on Physics" has been published by MM. A. Hermann et Fils, of Paris, at the price of 17 francs. As was the case with the first edition, the translation is the work of M. E. Davaux, and is based on the Russian and German editions. In this case, too, additions and notes have been made by MM. E. and F Cosserat. The previous edition was reviewed in the issue of NATURE for February 15, 1906 (vol. lxxiii., p. 362), to which reference may be made.

OUR ASTRONOMICAL COLUMN.

SCHAUMASSE'S COMET, 1911*h*.—From the Nice and the Arcetri observations of comet 1911*h*, on November 30, December 1 and 2, M. Fayet has calculated a set of elements, which is published in a supplement to No. 4541 of the *Astronomische Nachrichten*. The elements give February 5, 1912, as the date of perihelion passage, and, as will be seen from the extract from the ephemeris, given below, the comet is now getting nearer to both the earth and the sun.

Ephemeris 12*h.* (*M.T. Paris*).

The comet is travelling south-east through Virgo, and rises about three o'clock in the morning.

OBSERVATIONS OF COMETS.—In No. 4538 of the *Astronomische Nachrichten* Prof. Barnard publishes the results of his observations of Wolf's periodic comet (1911*a*) during the present return. The observations were made with the Yerkes 40-inch refractor, and show that the magnitude was about 14–15, the diameter from 5″ to 10″, and that the comet was a small and indefinite, although not diffused, object.

Positions of comet 1911*b* (Kiess), determined during July 13 to August 10 at Leipzig, are given by Dr. H. Naumann, who found the comet to be very diffuse and changeable in appearance.

In No. 4539 of the same journal Dr. Backlund discusses the observed and calculated places of Encke's comet (1911*d*) during the present apparition, with special reference to the question of acceleration and the mass of Mercury adopted in calculating the perturbing forces. Prof. Konkoly records the wave-lengths and intensities of the four bands 560, 546, 516, and 472 observed in Brooks's and Beljawsky's comets, showing that the second and fourth of these were relatively faint in Beljawsky's comet at the time of observation. Only the first, third, and fourth of these bands were recorded in the spectrum of Quénisset's comet on October 14.

In the *Gazette Astronomique* (Nos. 47–48) are reproduced drawings, made by M. Biesbroeck at Uccle, of comets 1911*c*, 1911*f*, and 1911*g* on October 17; the differences in form are very striking. That of Brooks's comet (1911*c*) is of the Morehouse type, with long envelopes developed in front of the nucleus sweeping out into a long, fairly narrow tail. The form of comet 1911*f* (Quénisset) is very different, the tail being emitted as a narrow straight jet from a point at the centre of the rear of the head. In Beljawsky's (1911*g*) we recognise the type of envelope seen in the case of comet 1910*a*, where the nucleus was located slightly within the front surface of a broad parabolic envelope.

THE DISTRIBUTION OF STARS OF DIFFERENT SPECTRAL TYPES.—Dr. Karl-Gustav Hagström publishes the results of an interesting investigation concerning the distribution of stars in space, from the point of view of their spectra, in No. 7, vol. xlvi., of the *Kungl. Svenska Vetenskaps-akademiens Handlingar*. He finds that his class α (fifth-type stars) shows a marked concentration about the equator of the Milky Way, and that his β type (Orion stars) are more numerous and more concentrated in the southern than in the northern hemisphere; but for solar and first-type stars, also for the later types, he can find no preferential grouping. Accepting Herschel's idea that the visible stars form a single system, and admitting that the non-concentrated types are inside the ring of such a system, it would appear from this investigation that the system is lenticular in form, the cooler redder stars being situated in the neighbourhood of the sun, and the hotter stars in the edge of the lens form. As the hotter stars also appear to be in the southern hemisphere, it would seem that the sun is located in the northern part of this stellar system.

DETERMINATION OF RADIAL VELOCITIES.—An important contribution to the study of stellar radial velocities appears in vol. x. of the Annals of the Cape Observatory—Spectroscopic Researches. It contains the results of the measurement and discussion of radial-velocity plates taken between November 7, 1903, and May 4, 1908, and deals with thirty-one stars of the third magnitude and brighter. The measurements of each line on each plate, and the wave-lengths of the comparison spectra, are very fully discussed, and it is shown that there is apparently a distinct variation of wave-length with spectral type, the thirty-one stars, for this purpose, being arranged in six successive groups. A comparison of the Cape results with those published, for the same stars, by other observatories is reassuring concerning the general trustworthiness of radial-velocity results; thus eleven out of the thirteen results given for α Tauri, determined at six different observatories, all lie between 51·7 and 55·9 km. per sec.

EARLY METHODS OF DETERMINING LATITUDE.—Among the publications of the Deutsche Seewarte of the Kaiserliche Marine at Hamburg has recently appeared a memoir entitled "Die Geschichtliche Entwicklung der Polhohen-bestimmungen bei den älteren Völkern," by Carl Schoy. It contains a history of the various methods of determining geographical latitude employed by the early astronomers to about the date 1250. The author makes no original contribution to our sources of knowledge; but he has made a careful survey of the existing sources and the work of modern scholars, and his explanatory comment, with numerous references, should be useful to those who are interested in the archæological side of the subject.

The memoir consists of five chapters, of which the first deals briefly with the earliest attempts at a solution of the problem, especially among the Chinese. The second chapter relates to the Greek astronomers, from Eudoxus to Ptolemy; in this period we find the earliest recognition of the change of latitude with locality. The contribution of Indian astronomers, which is next described, does not seem to have advanced the methods of observation, but was of the greatest importance in the development of trigonometry.

The last two chapters treat of the work of the Arab astronomers Al-Battâni, Ibn Jûnis, and Abul Hassan, of Morocco. The mediæval Arabs inherited the knowledge acquired by the Greeks and the Hindus, and are known to have possessed translations of the works of Euclid, Ptolemy, and Brahmagupta. But they also made notable progress on their own account. Abul Hassan, in particular, shows the greatest fertility of resource in inventing new methods, and succeeded in solving the most complicated problems in dialling. This, at least, would appear from his work; but, naturally, it is impossible to estimate the debt which he owed to his predecessors.

STARS HAVING PECULIAR SPECTRA.—While examining the photographs of the Henry Draper Memorial, the late Mrs. Fleming discovered an immense number of variable stars and other objects having peculiar spectra, and the finds have been from time to time recorded in the Harvard College Observatory Circulars. No. 167 of these probably completes the record of Mrs. Fleming's discoveries, and contains a list of thirty-one new variables, of which thirteen were found by her. It also gives a list of seven stars having peculiar spectra, of which Mrs. Fleming discovered five; in three cases $H\beta$ is bright, three others contain bright lines, one being a gaseous nebula, and the other has a normal fourth-type spectrum.

THE EVOLUTION OF MULTIPLE STARS.—The question of the evolution of double and multiple star systems is discussed, in the light of recent discoveries, by Dr. See in No. 4539 of the *Astronomische Nachrichten*. *Inter alia*, he states that such systems, having developed from spiral nebulæ of vast extent and slow motion of revolution, should show but little relative motion, and suggests that in such cases as β Cygni, α Tauri, &c., an effort be made to photograph the extremely faint residual nebulosity which, according to the hypothesis, may still surround the members of such systems.

MATHEMATICS IN ENGLISH SCHOOLS.

THE powerful and vigorous article on "Mathematics in English Schools" contributed to *Science Progress* for October by Mr. Charles Godfrey, headmaster of the Royal Naval College, Osborne, opens up a subject deserving the most attentive study on the part of everyone who is interested in the future progress of our race. As the author points out, modern civilisation stands on a foundation of applied mathematics; without mathematics the earth could not support its present population. But in England we have a ruling class whose interests are sporting, athletic, and literary; consequently not only is mathematics not a bread-and-butter subject except for those who are satisfied with this simple diet, but the work of the mathematician is ignored and even treated with contempt. And this in spite of the fact stated by Mr. Godfrey, that mathematics occupies a larger share of time in our school curricula than in those of other countries. The remedy proposed by Mr. Godfrey is that our teaching in schools should be based on the "outlook" value of mathematics, and should train our boys to appreciate the tremendous potentialities of the subject of which they are mastering the elements. At

present our teaching involves a large amount of disciplinary drill in subjects like algebra, which affords no outlook beyond that afforded by the examination value of the subject.

Mr. Godfrey finds that, whatever may be the real educational value of this training, we have no definite proof that it confers advantages which could not be at least equally efficiently derived from other studies. On the other hand, we have certainly failed in one thing: broadly speaking, we have failed to make mathematical thought enter as a main element into the life of the educated classes. More and more the affairs of life are being made amenable to mathematical treatment, and as it has turned out the development has been on lines divergent from the lines of schoolwork. In these developments, the study of the calculus has been the fundamental form in which mathematics is applied to the affairs of modern life. This study, however, does not grow out of the summit of school mathematics, but branches off low down the stem, and it is independent of formal geometry; a vigorous pruning of school algebra and arithmetic would in no wise prejudice the growth we want to encourage.

Mr. Godfrey, referring to the requirements of the non-mathematical schoolboy, compares the drudgery and drill of multiplying and dividing long algebraic expressions to the technique of piano-playing, which may be useful for the professional musician, but conspicuously fails to stimulate a taste for music in the average pupil. He finds that the time saved from this drill would amply suffice not only for the teaching of the calculus when its fundamental principles are divested of the unnecessary complications introduced by the consideration of transcendental functions, but that a stimulating course in mechanics can quite well be fitted into the curriculum which the mathematical as distinct from the science master can provide for the non-specialist schoolboy.

As regards statics the position is clear, provided that experimental methods receive due prominence. The case for dynamics is not so clear, and Mr. Godfrey's difficulties may perhaps receive confirmation from the disagreement which still exists among teachers regarding mass and weight, poundals and slugs. He would therefore propose to restrict the study to kinematics, which, as he points out, is really nothing more than geometry with the introduction of a time element. Many of Mr. Godfrey's suggestions have been under the consideration of the committees appointed by the Mathematical Association to inquire into the teaching of school mathematics, and the feasibility of the proposals to which he directs attention is proved by the fact that, in the French *lycées* for classical specialists, the proposed training in analysis is reached with a far shorter number of hours of schoolwork than is given to mathematics in England.

The views indicated very imperfectly in this abstract will doubtless be read with regret by disciples of the old school. But England's neglect of mathematics requires us to face many hard and unpleasant truths, and it is probably no exaggeration to say that at the present time a plea for the study of classics, even Latin and Greek grammar, would receive a favourable reception at the hands of a large section of the British public which would turn a deaf ear to any corresponding claim of the mathematician.

G. H. B.

THE HEALTH OF THE NATION.

THE sixth annual meeting of the National League for Physical Education and Improvement was held at the Mansion House on December 8, the Lord Mayor presiding. Letters of regret were read from the Archbishop of York, Lord Haldane, the Lord Chief Justice, and others. The first speaker was Sir Archibald Geikie, president of the Royal Society. He greatly approved of the objects of the league, which are to stimulate public interest in the physical improvement of the people, to lessen waste by coordinating agencies already established for this purpose, and starting them where none at present exist, to make better known the local powers already possessed by public authorities, and to promote fresh legislation where necessary. In a short, telling speech he pointed out that while the league was to be congratulated on the very rapid and excellent progress it had made during the six years in which it has been in existence, it has been, and still is, hampered by want of funds, a want which it is to be hoped will be remedied in the coming year by the aid of all those who have the health of the nation at heart.

Bishop Boyd Carpenter described more in detail the work of the league during the past year. The three subjects on which it had been particularly engaged were the need for a clean milk supply, organised physical recreation, and the dangers arising from the use of inflammable makes of flannelette. He showed that the league's work was not of a purely philanthropic nature—it was an effort at self-protection on the part of a great nation. It tried to protect children in their upgrowth and to prevent them, in various ways, from becoming a source of weakness to the community.

Prof. Bostock Hill, medical officer of health for Warwickshire, suggested that a national health week be instituted, culminating in a Health Sunday, when the churches might bring home to the nation the gospel of hygiene. Communal sanitation has resulted in a very considerable reduction in the death-rate of this country; but he pointed out that more than communal effort was now required, and that this could only be brought about by giving to the people individually a knowledge of what hygiene could do for them, and at the same time co-ordinating the services of all societies, private and public, towards this end. People must be brought to understand that hygiene consists in the spread of cleanliness, applied to air, food, earth, and the dwelling.

Lady St. Davids brought forward several practical suggestions, such as the formation of tooth clubs for toothless people, instead of boot clubs for bootless children, since the former were in more danger of injuring their constitution than the latter. She also pleaded for the closer cooperation of the nursing profession with all who were concerned in the promotion of the health of the nation.

THE ANALYSIS OF SPECIES.[1]

THE author of the paper referred to below has made an important pioneer contribution to the study of heredity in crosses between plants of widely divergent phylogeny, viz. reputed species of Linum, and has compared the results obtained from such species-hybrids with those obtained from the simpler varietal crosses. Statistical methods have been utilised for the expression of the characters examined, as in the work of Johanssen.

The general trend of the results is to show that even in cases where the composition of F_2 appears to present perfectly smooth variation between the two parental extremes, the behaviour in F_3 shows that the inheritance is in reality factorial, and can be most easily explained on Mendelian principles. The frequency with which the parental forms reappear is least in crosses of reputed species, and becomes more common with closer crosses until simple mono-hybrids are reached. The methods by which the data were obtained appear to have been above suspicion, both experimentally and statistically, while the important error from vicinism is said to have been excluded.

One possibility has perhaps been overlooked, namely. that while the inheritance of such a character as length of seed is probably determined by several allelomorphic pairs, yet the ultimate dimensions of the seed of any given plant, fluctuation having been evaluated, may be influenced through correlation with other similarly inherited characters, notably the dimensions of the fruit. The position of any plant in the frequency curve for a family is thus, apart from fluctuation, firstly determined by the factors which it carries, and secondarily by a deflection of the expression of those factors from the normal by somatic correlation.

The characters studied were the length and breadth of the seed, the length and breadth of the petals, and the

1 "Das Verhalten fluktuierend variiender Merkmale bei der Bastardierung." Von Tine Tammes, aus dem Botanischen Laboratorium der Universität Groningen. Extrait du Recueil des Travaux botaniques Néerlandais, vol. viii., Livr. 3, 1911.

petal colour, all of which received quantitative measurement, together with qualitative studies of the dehiscence of the fruit and the hairiness of the ovary walls. The article is illustrated by two photographs, and by ten diagrams which include nearly a hundred frequency polygons.

AMPHIBIAN FAUNAS OF SOUTH AFRICA AND MADAGASCAR.

IN discussing the relationships between the amphibian faunas of South Africa and Madagascar in the Annals of the Transvaal Museum for April, Mr. J. Hewitt accepts the theory of an early land connection between Australia, India, Madagascar, the Seychelles, and South Africa, which was sundered between Australia and Africa after the Lower Cretaceous, and was elsewhere broken up into islands in the early Tertiary. The connection between Madagascar and India persisted until the Eocene, or perhaps later, as an archipelago, and Africa may have been connected by swamps with Madagascar until the early Pliocene. Another land-bridge connecting South Africa and South America by way of the Atlantic is likewise accepted. The fauna of the whole area is considered to have had many features in common; but after the separation of Madagascar and the formation of the African continent the latter area was invaded by a Palæarctic fauna, which could not reach Madagascar. The fauna of that island accordingly seems to represent in a modernised form—with a few additions—the one originally common to the southern Ethiopian area.

The author then proceeds to discuss how the relations of the amphibian faunas of Africa, Madagascar, South America, and Australia can be explained on these suppositions. To follow him in detail would take too much space; but it may be mentioned that he is disinclined to accept the generic identity of the Malagasy boa-like snakes with South American types, and that he regards true frogs (Rana) as of African, and tree-frogs (Hylidæ) as of South American, origin. The two latter are stated to have attained their present distribution by crossing what is now Bering Strait, in opposite directions, after the sundering of the connection between Africa and South America (p. 37), Rana having thus reached South America from the north (p. 35). On the other hand, it is stated later (p. 38) that the Ranidæ are an Old World group "which crossed over to the Neotropical region at a time when the land-bridge was just beginning to give way, and when eventually they had travelled northwards as far as the Antillean bridge this was no longer complete." The discrepancy in the two statements requires explanation.

WATER SUPPLY IN AUSTRALIA.

THE great drawback to settlement in some parts of Australia is the frequent droughts that have to be dealt with. So far back as 1884 the New South Wales Government appointed a commission to consider the question of irrigation, and, as a result, a water conservation department was organised, and an experienced Indian irrigation engineer appointed to advise. As one result of this the construction of a dam across the Murrumbidgee River was decided on. This dam, known as the Burrinjack Dam, rivals in size and quantity of water impounded the famous Assouan Barrage across the Nile. The Murrumbidgee River for 200 miles above the dam runs its course principally amongst mountains, the higher peaks of which are covered with snow in winter. The catchment area at this point amounts to 5000 square miles, the rainfall varying from 20 to 70 inches a year. At the place where the dam has been constructed the whole of the river water passes through a narrow granite gorge, and consequently the minimum cost of construction, combined with the maximum stability, has been secured. For about 200 miles below the dam no irrigation works are needed, as the district through which the river flows is undulating and has a sufficient rainfall. Below this the river enters a flat country, with a diminished flow of water. Like some other rivers in Australia, the Murrumbidgee, instead of increasing in volume as it proceeds on its downward course to the ocean, actually diminishes, and becomes a small stream. This is due to the diversion of its water into shallow lagoons, where the evaporation caused by the fierce sun and percolation disposes of the greater part of the water. The dam is of concrete, 240 feet high and 784 feet long. It will back up the water in the main stream for 41 miles, and of two of its tributaries for 15 and 25 miles. Although the water supply is to be brought into operation at once, the dam has only been built up to 110 feet; the remaining 130 feet, it is expected, will take two years more to complete. For carrying on the works and providing for the staff employed a temporary township has been created provided with complete sanitary arrangements and medical attendance. An electric installation has also been set up for working the cranes and other machinery. A light railway 28 miles long has been constructed connecting the temporary township with the main line of railway from Sydney to Melbourne. The estimated cost of this work is 758,000*l*.

THE DIVINING ROD.

DR. L. WEBER, professor of physics in the University of Kiel, has published in the *Journal fur Gasbeleuchtung und Verwandte Beleuchtungsarten sowie fur Wasserversorgung* a copy of an address on the divining rod read by him at Flensburg in September last. Dr. Weber regards belief in the powers of water diviners as a form of antiquated superstition and gross error; he is of opinion that there is no evidence that the movements of the rod are due to any cause outside the diviner, who is the subject of self-deception. He bases this view on the results of careful investigation, but, in so far as the paper in question is concerned, only one instance of actual experiment is given (see below).

Dr. Weber mentions the results obtained by Herr von Uslar in the German African colonies, and thinks that the divining rod was, in this case, simply a magic staff which animated von Uslar's expedition to extraordinary exertions, and, more particularly, to deep boring with excellent results.

The experiment mentioned in the *Journal* is one performed at Flensburg before the Association of Gas and Water Specialists of Lower Saxony. Herr Léon, a well-known water diviner from Kiel, submitted himself to the blindfold test tried so frequently; he indicated two places in a room, in one of which his rod acted strongly, and in the other of which there was little or no action. He was then carefully blindfolded, turned round, and taken to the two places in irregular turns, when his rod gave corresponding indications to those obtained at first (when not blindfolded) in only two cases out of the six. The present writer has performed similar experiments, and always with similar results to those which Dr. Weber obtained with Herr Léon: he is, however, of opinion that they cannot be regarded as conclusive, since it is quite possible that, if the movements of the diviner's rod are due to an objective cause, the blindfolding may influence the nervous condition of the water diviner in such a way as to render him a less efficient "water indicator" than he would be in ordinary circumstances. On the other hand, it must be remembered that Herr Léon accepted the conditions of the experiment, and when a scientific man undertakes to investigate an apparently mystic process, such as water finding, he cannot be expected to do more than lay down conditions which appear to him reasonable and are accepted by the diviner.

J. W.

NEW MECHANICAL ENGINEERING LABORATORY OF THE MUNICIPAL TECHNICAL INSTITUTE, BELFAST.

ABOUT eighteen months ago the Corporation of Belfast authorised the preparation of plans and the installation of a teaching equipment suitable for the scientific training of mechanical engineers. The plans for this work were at once put in hand, and the installation has been carried out to the designs and under the direction and superintendence of Prof. J. H. Smith, head of the mechanical engineering department of the institute.

The laboratory was opened by Prof. J. Perry, F.R.S., on November 24 in the presence of a large company, including members of the Corporation, prominent manufacturers, and business men. The dimensions of the laboratory are 141 feet by 42 feet, with a mean height of 20 feet. The building is fitted with two travelling cranes. It has an upper floor and a lower floor, between which are placed the lines of shafting, the piping for engines, and all similar accessories.

The installation includes steam-driven machines, electric generating plant, oil engine, gas engine, petrol engine, centrifugal pumps, turbines, and refrigerating machine. There is also a full range of smaller testing appliances necessary for the complete training of an engineer.

The detailed list of appliances is a very lengthy one. The steam generating section includes a Lancashire boiler measuring 30 feet by 8 feet, and a marine-type boiler measuring 14 feet by 11 feet, together with pumps, meters, economiser, superheater, feed-water heater, induced draught fan, pressure and temperature indicators, &c.

The steam section comprises a steam engine of the horizontal cross-compound type of 60 horse-power, built by Messrs. Combe Barbour, of Belfast; a 20 horse-power high-speed generating set built by Messrs. W. H. Allen and Co., of Bedford; a 15 kilowatt Parsons steam turbo-alternator; a De Laval turbine of 20 horse-power; a steam pump and a condensing plant.

The hydraulic section is exceptionally well designed and equipped, and includes a motor-driven high-lift turbo-pump, cast-iron channels, tank, tumbling bay, venturi meter, pitot tubes, Thomson turbine, Girard turbine, Pelton turbine, and an apparatus for experiments on pipe friction.

The testing of materials section contains a Richlé testing machine of 68 tons capacity, on which experiments may be made in tension, compression, bending, and torsion; an Adie machine for cement testing; a fatigue testing machine, designed by the professor of mechanical engineering (Dr. Smith); appliances for the microscopical examination of metals; a "hardness of metals" tester; and various other appliances.

The section of internal-combustion machines includes a gas engine, a suction-gas plant, an oil engine, and a petrol engine. Additional fittings are a main switchboard of special design, an air-compression plant, a refrigerating plant, and an electrical direct-driven fan of "Sirocco" pattern. There are, in addition, all the necessary subsidiary appliances, such as calorimeters, micrometer, and other gauges, indicators, anemometer, &c.

The workshop adjoining the mechanical engineering laboratory is exceptionally well fitted with up-to-date machines, amongst which are a universal milling machine, a high-speed planer, a high-speed screw-cutting lathe, a boring and surfacing lathe, a Hendy-Norton screw-cutting lathe, a vertical automatic drilling machine, a shaping machine, together with grinding machines, brazing apparatus, vices, and other adjuncts found in a well-equipped machine shop. Adjoining the machine shop is a pattern shop, which contains a hand-turning lathe, circular saw, band saw, universal wood-cutter, and the requisite supply of benches.

The Plenum ventilating and heating plant also forms part of the mechanical engineering equipment of the institute, and from time to time it is used in the instruction of students and for experimental purposes.

Photo.] New Mechanical Laboratory, Municipal Technical Institute, Belfast. [*A. R. Hogg.*

The city of Belfast can now claim to possess a mechanical engineering equipment as comprehensive as that of any technical institution of the United Kingdom.

SCIENCE EXAMINATIONS AND GROUPED COURSE CERTIFICATES.[1]

CIRCULAR 776 was issued by the Board of Education on June 20, 1911, which date was near the commencement of the long vacation, and made it practically impossible for the governing authorities of technical institutions to introduce any necessary amendments into the schemes of instruction for the present session. In its general arrangements the scheme is, without doubt, excellent, and teachers familiar with certain of the local group course systems will probably at first conclude that it will fit the modern conditions of the group course system very accurately. More careful study, however, reveals the fact that there

[1] From an address delivered before the Association of Teachers in Technical Institutions on November 11 by Mr. Barker North, ex-president of the Association.

are enormous difficulties in the way of its immediate adoption, and the smaller technical institutions in particular will be very hard hit by the condition bringing the scheme into operation during the present session. These difficulties exist with reference to both day and evening work, but it is in connection with the latter that the matter is one of great urgency, and the following remarks will therefore deal only with the principal changes affecting evening instruction.

A. *Changes in Subjects and Stages foreshadowed in the Circular.*—(1) The abolition of all Stage I. and practical examinations; (2) the abandonment of all examinations held by the Board in the following subjects: sound, light, geology, mineralogy, physiology, general biology, zoology, botany, navigation, nautical astronomy, physiography, agricultural science, hygiene, and elementary science of common life; (3) principles of mining becomes coal-mining only; (4) for the purpose of constituting examining boards, to include teachers in technical schools, the subjects retained will be grouped as follows: (*a*) pure and applied mathematics, (*b*) engineering, (*c*) physics, (*d*) chemistry, (*e*) mining and metallurgy; (5) there will be two stages only in each subject, viz. "lower," corresponding to the old Stage II. examinations, and "higher," the standard being intermediate between the old Stage III. and honours examinations; (6) in each grade of each subject, one paper only will be set, with the exception of "higher" pure mathematics, in which two papers will be given.

B. *Conditions of Admission.*—(1) A fee of 3*s*. 6*d*. must be paid by the candidate for each stage in each subject; (2) candidates must be over seventeen years of age on July 31 following the examination; (3) students taking full-time *day* courses will only be admitted under special conditions; (4) in the following subjects: theoretical mechanics (solids), theoretical mechanics (fluids), applied mechanics (materials and structures), applied mechanics (machines and hydraulics), heat engines, heat, magnetism and electricity, inorganic chemistry, organic chemistry, and metallurgy, a candidate for admission to the higher examination must furnish a certificate of having completed a satisfactory amount of laboratory work, and submit laboratory note-books signed and certified by the teacher.

C. *Records of Successes.*—The issue of personal certificates will be discontinued, result lists only being published by the Board, with the following exceptions: (1) certificates for the present will be issued for coal-mining; (2) personal certificates to successful candidates at *higher examinations only*, will be awarded provided (*a*) "that they have previously received appropriate group course certificates" endorsed by the Board, (*b*) "that the examination has not been approved in connection with the course for a certificate"; (3) successes in higher and lower stages, and in other approved external examinations, such as the City and Guilds Institute, may be recorded upon grouped course certificates endorsed by the Board, but successes at internal examinations may not be separately recorded.

After studying the conditions detailed above, most teachers will no doubt come to the conclusion that evening students will not be likely to sit for the Board's new examinations. The institution of the 3*s*. 6*d*. fee will alone act as a sufficient deterrent, especially in the case of a group course student wishing to take several examinations, but this, when combined with the fact that a record of success can only be obtained by complying with certain very difficult conditions, must reduce the number of candidates almost to the vanishing point. The past few years has been a transitional period, and elaborate group courses, suited to the local industries, have been adopted by most schools in place of the system of detached classes suited to the Board's examinations. In most places, however, the syllabuses of instruction are modelled on the syllabuses of the Board's science examinations, no doubt with the view of attracting certain students who still place faith in the certificates awarded by the Board; and this is the case particularly with smaller institutions, where the local certificates have proved so far of little value. This must continue until some means can be devised of giving a definite and fairly uniform value to the certificates awarded by different institutions for corresponding years of a group course.

Undoubtedly the country is ripe for the introduction of a national group course system, and we therefore turn expectantly to the scheme which the Board suggests.

The Scheme of Grouped Courses in the Circular.—For evening students the Board suggests the classification of courses into three grades:—(1) Junior courses (two years), for youths leaving elementary schools at fourteen. (2) Senior courses (three years), for students who have taken either (*a*) a junior course, or (*b*) a three years' course at a secondary or higher elementary school. (3) Advanced courses (two years), for students who have taken the senior course. The Board is prepared to endorse certificates in senior and advanced courses only under the following conditions, amongst others:—(1) The group course system *must previously have been approved* by the Board, who must also be satisfied with the equipment of the school, and the steps taken to admit only properly qualified students to the course. (2) No unendorsed certificates may be issued by the local authority.

The local certificates of a few of the larger institutions in the country have already become of some value to the holders in the local industries, and therefore the question of endorsement is of little immediate importance to these places, but in the case of the smaller institutions, in view of the fact that the local certificates are not of great value, if any, where they are already given, the question of endorsement becomes of prime importance. A cursory glance at calendars of various technical institutions will show that, although each may have many excellent features, such a variety exists in the construction of the courses that the Board cannot conscientiously approve many of these, and thus a grave injustice must be done during the next few years to a great number of students who have been working towards a definite objective. Take the first three years' courses at Manchester, Bradford, Leeds, and Liverpool in chemical industries as examples. The total possible student hours in the three years are, respectively, Manchester, 660 hours; Bradford, 540 hours; Leeds, 697 hours; Liverpool, 630 hours; sufficient variation, one would think, to result in a very different standard of attainment at the end of the Board's senior course scheme, each institution admitting at the age of sixteen years. The division of the time mentioned above is apportioned as follows:—

—	Manchester	Bradford	Leeds	Liverpool
	hours	hours	hours	hours

It should be mentioned that at Bradford the student takes preliminary mathematics, elementary physics, and Stage I. inorganic chemistry for two years in the branch technical schools as a preliminary, whereas the other institutions all begin with Stage I. inorganic chemistry in the technical courses mentioned above. Further, in the three years' course above, Bradford completes Stage III. inorganic chemistry, the other institutions completing Stage II.; in organic chemistry, Manchester and Leeds complete Stage II. work, Bradford Stage I., and Liverpool does not include organic chemistry in the three years' course.

An examination of some 200 calendars of institutions throughout the country has shown that the examples given

are typical of the group course system, a feature which is not surprising when we consider the way in which the course system has developed. It illustrates, perhaps, more clearly than any other fact the lack of "guidance from the mind that sees the needs of the country from the greater and national point of view." Cast-iron schemes and syllabuses are not required: the Board's rigid syllabuses have during recent years proved a failure from the teacher's point of view; but surely some greater degree of uniformity can be obtained than is shown above, whilst retaining the necessary pliability to suit local requirements of the industries. Before any uniform system of endorsement of certificates can be introduced, coordination of the courses in different institutions must be secured by the standardisation of the courses, as a guide to the standard to be arrived at in any one year, or at the end of a given course. A very grave injustice will be done to a great number of students, and, further, there will be a danger of the loss of many students, unless the conditions outlined in the circular are modified, either (1) by delay in the operation of the scheme for one or two years, or (2) by modifications of the conditions, such as reduction of the entrance fee, the granting of certificates by the Board, particularly in the lower stage, and the revival of examinations in such subjects as light and natural sciences, during the transitional period that must ensue until institutions can come into line with the new requirements.

The time is opportune, too, for revision of the award of Government grant on the work done by evening students. Local authorities are sufficiently hard pressed at the present time without taking over the burden of the cost of examination systems, and the time has arrived for allocating an increased amount of money in the form of a capitation grant for those taking group courses, somewhat on the lines of the grant made at present for day courses in technical institutions, thus differentiating between group courses and single-subject courses. Teachers are convinced that three nights per week, under present conditions of daily employment, are too much in the cases of youths under eighteen, and up to the end of the second year in the senior course the Board might reasonably make the full grant for two evenings (five hours) per week, extending over a thirty weeks' session, instead of encouraging, as at present, courses which are overburdened, for the local authority cannot afford to reduce the number of hours per week in the institution expected from the student, owing to the loss of grant which this would entail. A better grounding in the elementary branches of the work would at the same time undoubtedly be secured.

As to the best method of carrying out a national system of examinations, which is absolutely independent of centralised examinations such as those of the Board of Education, and City and Guilds Institute, the feeling is growing in some quarters that this will be most successfully accomplished by the cooperation of county education authorities with the local education authorities in county boroughs, to form examination boards of teachers and representatives of the local industries, acting as external examiners or assessors in conjunction with the teachers in the institutions of a given area as internal examiners. Such boards would be more in sympathy with the local requirements than any central board could possibly be, and the Board of Education, through its inspectorate, and a National Examination Board should be able to maintain a moderately constant standard throughout the country once the system is in thorough working order. Such a National Examination Board should contain representatives, who should be teachers, from the local examination boards.

Each year in a student's work marks a distinct stage in his career, and this should be recognised on successful completion of the work of each year by the award of a local certificate or record, to be exchanged at the end of the course for the full endorsed certificate, giving a national stamp, or hall-mark, to the work. At the same time, it is worth consideration whether certain single-subject courses of a highly technical character are not worth the award of a special endorsed certificate, particularly in cases where the student is able to take up the higher work without passing through the preliminary grind of the earlier years, or in cases where the subject-matter does not readily adapt itself to inclusion in a course. There is undoubtedly the need for a national evening course system, so that the smaller institutions may readily and naturally feed the larger, in which the more advanced work will be concentrated, and so that this work may lead up systematically to the day diploma work of our specialised technical institutions.

INDUCED ACTION OF LEUCOCYTES.[1]

SCIENTIFIC workers may like to have a brief account of some recent researches which, I think, are likely to be of both theoretical and practical interest. The researches commenced nearly five years ago in a special study of leucocytes by a method devised by my brother, Mr. H. C. Ross, and myself. This consists in placing liquid blood under a cover-glass, not, as usual, upon another surface of glass, but upon a bed of transparent jelly with which various reagents, including stains, have been mixed. The original object of the method was to try to cultivate human leucocytes *in vitro*. At first careful studies of the rate of absorption of stains by the leucocytes under various chemical conditions of the jelly were made by Mr. Ross. Two years later he found that extract of hæmal gland, extracts of apparently many dead and decomposing tissues, and globin, when mixed with the jelly, force a large proportion of the leucocytes to divide before the eyes. Subsequently, he and his assistant, Dr. J. W. Cropper, ascertained by a series of lengthy studies that many of the substances which possess this property (in different degrees) belong to the amidine grouping. They have found, also, that a second series of substances, though by themselves they cannot produce division of leucocytes, have the power of augmenting very greatly the power of the former group of substances to do so. They give the names *auxetics* and *augmentors* to the two groups respectively. The principal auxetics are extracts of organs, creatine, xanthine, creatinine, guanidine, benzamidine, theobromine, acetamidine, caffeine, theophylline, methylamine, ethylamine, propylamine, &c., and certain aniline dyes. Some of the augmentors are various alkaloids, atropine, choline, cadaverine, neurine, &c.

The technique, though simple, requires considerable care. If a stain such as polychrome methylene blue is added, the cells become coloured progressively as the division advances. All the varieties of the human leucocytes can be made to divide; but the technique is slightly different for each variety. The proportion of cells affected in a given preparation of blood varies according to perfection of technique up to, say, 80 per cent.; but as death occurs rapidly, especially if stain be used, it usually overtakes a large proportion of them before the division has been completed. After about twenty minutes all the cells die, and by that time the process is complete in only a small percentage. Efforts to keep the cells alive longer upon these medicated jellies or in solutions of auxetics have not yet been very successful and would not be easy. After their death the leucocytes give up again most of their stain, and the jelly preparation rapidly spoils; but a method has been found of making (with some difficulty) permanent specimens of such of the blood as adheres to the cover-glass by fixing the whole preparation with osmic acid vapour, and then freezing and picking off the cover-glass from the bed of jelly.

To watch the same cell passing through the whole process requires an accurately adjusted warm stage or microscope-incubator and considerable patience, because the cell which we happen to select for observation will most probably belong to the majority which die before completion of the division; but partial division can be easily witnessed. If, however, the specimen is incubated for ten minutes, and is then surveyed rapidly from field to field, numbers of the leucocytes caught in all stages of the process can be readily seen. The fixed films just referred to show exactly the same objects, but enable us to examine them repeatedly and at leisure. And in both these cases the dividing forms are so numerous and similar that there

[1] From a paper read at the meeting of the Pathological Section of the Royal Society of Medicine on November 7 by Sir Ronald Ross, K.C.B., F.R.S.

can be no question of their being exceptional artefacts or distortions, such as may sometimes simulate almost anything. Division of the mononuclear variety of leucocytes is produced and studied the most easily.

In films in my possession numerous examples of dividing mononuclears fixed at all stages demonstrate (together with observations of the jelly preparations) the following steps in the process. In a few minutes after the blood is drawn from the subject and mounted the round, so-called nucleus becomes oval and then kidney- or bean-shaped, leading on rapidly to the outline of two circles cutting each other, and, lastly, touching each other in a "figure of eight." When the process is about half complete, and if the direction of division is parallel to the surface of the jelly or glass, another phenomenon is seen. About four to eight finger-like processes, radiating from the point midway between the centres of the two circles, are protruded or divided off, giving the whole body roughly the appearance of an ant, of which the head and abdomen are simulated by the two spheres and the legs by the processes just mentioned. Such forms are numerous and characteristic; but, of course, when the direction of division happens to lie at an angle to the surface, they are foreshortened, or may be distorted by the pressure of the jelly. As the division proceeds the processes are retracted into each daughter sphere, until the final figure of eight is produced.

If polychrome methylene blue is put in the jelly the cells become coloured progressively as the division advances. At first, after a few minutes, the so-called cytoplasmic, or Altmann's, granules take a purple tinge; then the so-called nucleus becomes a pale blue, and last of all the so-called nucleolus is stained, after which, apparently, the cell dies. As the so-called nucleus proceeds to take the hour-glass and figure-of-eight forms, strands of coloured substance are seen, especially in the fixed films, passing between the two daughter spheres, and such connections are maintained until complete dissociation occurs. The behaviour of the so-called nucleolus is not easy to follow, because, as just noted, it does not stain until the cell dies and further division is checked. On the other hand, the behaviour of the so-called cytoplasmic granules must be described as very curious. In the middle of the division they are found to number about eight (when they can be easily counted) and to lie, each one, at the end of one of the finger-like processes mentioned above; and appearances suggest that half of each granule is distributed to one daughter cell and the other half to the other daughter cell. No distinct chromosomes are seen at any stage *inside* the so-called nucleus; and there appears to be no sign of astral fibres, though perhaps the finger-like processes may be interpreted as being bunches of these fibres which have not been rendered individually visible by the process of staining employed. On conclusion of the process the so-called cytoplasmic granules appear to be equally distributed between the two daughter cells, and to place themselves on the outer surface of the so-called nucleus of each, that is, in the position in which they were seen in the original parent cell. Apparently asymmetric forms are also frequently seen, but need not be described here.

Such seem to me to be the facts as observed by myself in preparations shown or given to me by Mr. Ross and Dr. Cropper. I will not touch here upon the similar divisions of the so-called polymorphonuclear leucocytes, which have also been already described and figured by Mr. Ross. Nor will I attempt to reconcile the observations with current cytological teaching, even as regards the division of leucocytes. Very probably different methods of staining may bring them, at least partly, into closer conformity. Though engaged for years in the study of blood I have never seen these forms before, nor, indeed, have I ever seen in any ordinary preparation what could certainly be called a dividing leucocyte. I have been shown bodies claimed to be such; but these are admittedly so rare that they are open to the usual logical fallacies connected with very exceptional observations. The observations here referred to are not open to these fallacies. As I have said, the dividing forms are so numerous and characteristic that we can have no doubt that they really are dividing forms—whatever other observations or theories may be on record. It seems to me, therefore, that we are now compelled to admit two new facts:—(1) that large numbers of human leucocytes can be made to divide *in vitro*; and (2) that this division occurs entirely, or at least specially, in the presence of certain chemical substances.

In 1900 J. Loeb showed that parthenogenesis can be induced in the eggs of sea-urchins (Arbacia) by the addition of a definite proportion of MCl_2 to sea water; and since then many workers have studied such phenomena among other animals, while Wassilieff has used hyoscyamine, nicotine, and strychnine for similar researches. The independent observations now recorded would appear to extend cognate principles to body cells by showing that the division of leucocytes may be suddenly forced on at a great rate and in a few minutes by the absorption or presence of appropriate chemical agents, and may perhaps be inhibited by other chemical agents. The author added some remarks on the application of these observations to the genesis of tumours, and a discussion followed.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. W. Bateson, F.R.S., honorary fellow of St. John's College, Cambridge, and director of the John Innes Horticultural Institution at Merton, Surrey, has been appointed the next Herbert Spencer lecturer. The subject of the lecture, which is announced to be given on Wednesday, February 28, 1912, will be "Biological Fact and the Structure of Society."

The following courses of lectures and laboratory instruction in mathematics, astronomy, and physical science have been announced for next term, which begins on Monday, January 22, 1912:—Prof. Esson, F.R.S., will lecture on the comparison of analytic and synthetic methods in the geometry of conics; Prof. Love, F.R.S., on rigid dynamics; Prof. Elliott, F.R.S., on elliptic functions and on the theory of numbers; Prof. Clifton, F.R.S., on optics and acoustics; Mr. J. Walker, on double refraction and polarisation of light. Practical instruction in physics will be given by Prof. Clifton, Mr. J. Walker, Mr. I. C. Griffith, Mr. O. F. Brown, and Mr. G. H. Clough. Prof. Townsend, F.R.S., will lecture on electromagnetic induction; Mr. E. S. Craig, on mechanics and physics. Practical instruction in the electrical laboratory will be given by Mr. F. B. Pidduck, Mr. E. S. Craig, Mr. H. T. Tizard, Mr. S. Smith, and Mr. W. B. Gill. Prof. C. F. Jenkin will lecture and give practical instruction on strength of materials and thermodynamics; Mr. D. R. Pye will lecture on drawing, for engineering students; Prof. H. H. Turner, F.R.S., will lecture on elementary mathematical astronomy.

DR. H. BASSETT, demonstrator and assistant lecturer in chemistry at the University of Liverpool, has been appointed professor of chemistry at University College, Reading.

DR. W. R. BOYCE GIBSON, lecturer in philosophy at the University of Liverpool, has been appointed by the council of the University of Melbourne to the chair of mental and moral philosophy.

THE President of the Board of Education has appointed Mr. L. A. Selby-Bigge, C.B., to be permanent secretary of the Board when that post is vacated by Sir Robert Morant, K.C.B., on his appointment to the Insurance Commission. Since 1908 Mr. Selby-Bigge has been principal assistant secretary of the elementary branch of the Board.

THE council of the Royal Horticultural Society has requested the following gentlemen to act as a committee to inquire into the desirability of establishing a National Diploma in Horticulture, and to recommend what steps, if any, should be taken for the purpose:—the Rt. Hon. A. H. Dyke Acland, Prof. W. Bateson, F.R.S., Mr. E. A. Bowles, Mr. F. J. Chittenden, Prof. J. B. Farmer, F.R.S., Mr. C. R. Fielder, Mr. W. Hales, Mr. J. Hudson, Prof. Keeble, Sir Daniel Morris, Lieut.-Colonel D. Prain, F.R.S., Mr. H. J. Veitch, and Mr. W. P. Wright.

THE London County Council has arranged to hold its sixteenth annual Conference of Teachers on three days, Thursday, January 4, Friday, January 5, and Saturday,

January 6, 1912. The meetings will be held at Birkbeck College, Bream's Buildings, Chancery Lane, E.C. There will be addresses and discussions under the heads of specialisation in schools; chalk, brush, and pencil work in elementary schools; the doctrine of formal training (mental discipline); the treatment of backward children; and educational experiments in schools. No charge will be made for admission to the conference. Application for tickets of admission should be made to the Chief Inspector, London County Council, Education Offices, Victoria Embankment, W.C.

IT is announced in the issue of *The London University Gazette* for November 29 that a donation of 1000*l*. has been made by Mr. and Mrs. Walter Baily, in celebration of their golden wedding, for the purpose of rearranging and decorating the interior of a portion of University College. From the same source we learn that the Galton Laboratory Appeal Fund now amounts to 2629*l*. 15*s*. 6*d*. The list of donations, many of which are conditional on the buildings being commenced within two years, includes gifts of 500*l*. from Mr. W. E. Darwin, and Prof. Karl Pearson, F.R.S., and Mrs. Pearson; 250*l*. each from Prof. Arthur Schuster, F.R.S., and Mr. E. G. Wheler; and 100*l*. each from the Earl of Rosebery, Viscount Iveagh, Mr. A. F. Butler, Major Leonard Darwin, the Hon. Rupert Guinness, and Major E. H. Hills, F.R.S.

AN interesting experiment is being tried by the local education authority of Plymouth with the view of arousing an interest in the study of science among the children in its schools. On December 8 Mr. C. Carus-Wilson lectured to five thousand children in the Plymouth Guildhall, taking "Volcanic Outbursts" as his subject. Each child paid one penny for admission to the lecture, and it is expected that no contribution from the rates will be necessary to meet the expenditure incurred. The children seem to have been thoroughly interested, and the education authority is likely to arrange a series of similar lectures in the future. Descriptive accounts of natural phenomena, when judiciously illustrated, appeal to most children, and many men of science trace their first enthusiasm for their subject to a good lecture, supplemented by telling experiments. The Plymouth experiment deserves to be copied in other large towns.

IT is not clear from the reports in the daily papers of a meeting held at Brighton on December 12 whether the intention is to establish a university or a university college in the town. *The Times* reports that the meeting was "in furtherance of the movement to make Brighton a university town," while *The Morning Post* states that at the meeting (over which the Mayor of Brighton presided) "the proposal to establish a college of university rank for the county was unanimously approved." There is, of course, a vast difference between the two proposals, but apparently it is a university college which Brighton has in mind, and not a university. Resolutions approving of the principle of the establishment of a university college for Sussex, and the appointment of general and executive committees, were carried unanimously at Tuesday's meeting. The Mayor of Brighton was elected chairman of the executive committee, and Mr. W. H. B. Fletcher, who has taken a prominent part in the educational affairs of West Sussex, vice-chairman.

AN interesting account of the way in which American agricultural experiment stations come into contact with the farmer is given in Bulletin 208 of the Agricultural Department of the University of Wisconsin. Crop demonstrations are arranged on twenty farms connected with various public institutions throughout the State, making use of seeds bred at the experiment station, and of methods of cultivation and manures that previous experiments had shown to be advantageous. The fields selected for these demonstrations are, so far as possible, chosen alongside of the public highways, where the operations and results can be seen by the farmer throughout the whole season as he drives to and from town. The local papers also contain accounts from time to time of the work done and the appearance of the crop. Some time during the summer, when the crops are at their best, a demonstration picnic is arranged, to which large numbers of farmers are invited, the average attendance last year being 320. These meetings occupy an entire day, and a definite programme is arranged dealing with six to eight subjects centring round the field work. The effective feature is the fact that all the practices suggested to the farmer are illustrated in operation on the farm, and the crops are there to show in concrete form what the results have been. The influence of the work is very great, many farmers putting the new methods into operation at once.

THE December issue of *The Reading University College Review* is one which reflects credit on the college. The most interesting feature to readers in general will be the forty pages of notes on the multifarious activities of the institution. From these we learn that the entry of new students for the present session was very satisfactory. The number of students taking degree courses is 114, of whom 44 belong to the faculty of science and 6 to the Department of Agriculture. During the previous session 80 students received instruction in the dairy institute, in which connection it is interesting to record that at the annual meeting of the Berks. and Oxon. Chamber of Agriculture the following resolution was passed:—"The Board of Agriculture having decided to establish a central research station for dairying, we, the Berks. and Oxon. Chamber of Agriculture, strongly urge that University College, Reading, which is already in close touch with agriculturists and farmers in Berks. and the adjoining counties, should be selected as that centre. Our contention is based on the fact that the college is situated in the centre of a large dairying district, and that in Reading it has the headquarters of this Chamber and of the Berks. and Adjoining Counties Dairy Farmers' Association, where it can readily consult the farmers of the district. Believing that such close relations are essential to any scheme of agricultural development, we are anxious to see advantage taken of the exceptional facilities afforded in Reading."

AT a dinner of the Clothworkers' Company held on December 6, the President of the Board of Education, replying to the toast of the Houses of Parliament, referred to the generous assistance rendered by the great City companies to the promotion of facilities for higher education in this country. The President said he found that the Goldsmiths' Company contributed 50,000*l*. to the new engineering buildings of the Imperial College of Science and Technology. The Drapers' Company contributed 10,000*l*. to the building fund of the new college at Bangor, and this year the Drapers' Company contributed 23,000*l*. to the physiological laboratory at Cambridge and 15,000*l*. to the University of Sheffield. This year the Clothworkers' Company contributed 5000*l*. to the textile industries department at Leeds University. The Merchant Taylors' Company maintain the Merchant Taylors' School, the Mercers' Company are identified with St. Paul's School, the Fishmongers' Company with the Gresham College, the Skinners' Company with Tonbridge School, and the Haberdashers' Company with Aske's Foundation. The Clothworkers' Company are second in the list of donors to the City and Guilds of London Institute. Words failed him, Mr. Pease said in conclusion, to commend sufficiently their liberality and generosity in the interests of education. The Clothworkers' Company has equipped the textile and dyeing department of Leeds University to the extent of 161,000*l*., and 75 per cent. of its income is contributed to the promotion of education.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 7.—Sir Archibald Geikie, K.C.B., president, in the chair.—Miss I. B. **Sollas** and Prof. W. J. **Sollas**: Lapworthura: a typical brittlestar of the Silurian age; with suggestions for a new classification of the Ophiuroidea.—Leonard **Hill** and Martin **Flack**: The physiological influence of ozone. Ozone, in concentrations of one part in a million and more, acts as an irritant to the respiratory tract, and diminishes the respiratory metabolism, as shown by the lessened output of carbonic acid and the diminished fall in body weight, which occur both during the period of administration and for some time after. Concentrations of several parts per million cause acute inflammatory congestion of the lungs, and

animals die as the result of this if kept long exposed to the ozone. Concentrations which can just be sensed by smell, i.e. far less than one part per million, have no injurious effect, and can be used safely in systems of ventilation. Injurious concentrations of ozone, by producing irritation of the air-passages, cough, and headache, compel anyone exposed to such to remove himself from the influence of ozone before any serious damage is done to the respiratory tract. Very low concentrations of ozone mask disagreeable smells, give a fresh quality to air vitiated by such smells, and vary the depressing monotony of air which is artificially warmed. Ozone may possibly have some use in the treatment of disease of the respiratory tract if used in concentrations which produce a slight irritation, and thus bring more blood and tissue lymph to the part.—H. R. **Dean**: The factors concerned in agglutination. (1) If, to a mixture of sheep corpuscles with antiserum so dilute that no agglutination is visible be added a solution of globulin obtained from normal guinea-pig serum, the corpuscles are markedly agglutinated. By use of suitable controls it can be demonstrated that neither the globulin solution nor the dilution of antiserum employed are of themselves capable of agglutinating the corpuscles. (2) The substance present in the globulin solution which aids agglutination is relatively thermostable, and its presence can be demonstrated in whole heated guinea-pig serum. (3) Corpuscles, sensitised and washed to remove free antibody, can be agglutinated by the globulin solution. If, after agglutination has taken place, the corpuscles be removed with a centrifuge, the supernatant fluid can be shown to have lost its agglutinating property. (4) The agglutinating power of an extremely dilute antityphoid serum can be increased by addition of globulin solution. Adding this to a mixture of emulsion of *B. typhosus* with a dilution of antiserum too weak by itself to agglutinate bacilli, distinct agglutination can be obtained. (5) Formation of a specific precipitate by interaction of serum and homologous antiserum depends on the presence in the mixture of a relatively large amount of antiserum. If to a mixture of serum with antiserum so diluted that it is no longer able to produce a precipitate is added the globulin solution, a definite turbidity is produced. (6) Probably agglutinating serum (antiserum) contains two factors, both of which are necessary to produce agglutination; one of these is the specific antibody, the other is a non-specific substance, possibly serum globulin. The interaction of antigen with antibody produces an aggregation of molecules of non-specific substance, which may ultimately result in formation of definite turbidity. This process of aggregation of the particles of non-specific substance is an essential part of the process of agglutination. It is possible to make a dilution of an antiserum which contains sufficient of specific anti-substance, but not sufficient of non-specific substance. Deficiency in non-specific substance can be made up by addition of globulin solution obtained from normal serum. —Arthur **Harden** and S. G. **Paine**: Action of dissolved substances upon the autofermentation of yeast. All dissolved substances which plasmolyse the yeast-cell also cause a large increase in the rate of autofermentation. Substances such as urea, which even in concentrated solution do not produce plasmolysis, have no accelerating effect. Toluene produces a similar effect to concentrated salt solutions. The effect produced by salts is probably a direct result of the concentration of the cell contents due to plasmolysis, but in the case of toluene it is possible that some other factor (such as disorganisation of the cell, or hormone action) is concerned.—Prof. G. **Dreyer** and W. **Ray**: Further experiments upon the blood volume of mammals and its relation to the surface area of the body. —G. W. **Ellis** and J. A. **Gardner**: The origin and destiny of cholesterol in the animal organism. Part viii.—On the cholesterol content of the liver of rabbits under various diets and during inanition. The authors have made analyses of the livers of a number of rabbits fed on the following diets:—cabbage, bran which had been extracted with ether, extracted bran to which cholesterol had been added. In some cases the cholesterol, instead of being given with the food, was injected in olive-oil solution into the peritoneal cavity. For animals fed on extracted bran alone the total liver cholesterol per kilog. of body weight is very constant, but when cholesterol is given with the food or injected into the peritoneal cavity a considerable increase takes place. A similar increase was observed in the liver cholesterol during inanition, when the animal lives on its own tissues. The percentage cholesterol content of the livers of newly-born animals is of the same order as that of normally fed adults. The results afford support to the working hypothesis, with regard to the origin and destiny of cholesterol in the organism, put forward some time ago by the authors, viz. that cholesterol is a constituent constantly present in all cells, and when these cells are broken down in the life process the cholesterol is not excreted as a waste product, but is utilised in the formation of new cells. A function of the liver is to break down dead cells, *e.g.* blood corpuscles, and eliminate their cholesterol in the bile. After the bile has been poured into the intestine in the processes of digestion, the cholesterol is reabsorbed, possibly in the form of esters, and carried in the blood stream to the various centres and tissues for reincorporation into the constitution of new cells.

Physical Society, November 24.—Dr. A. **Russell**: The maximum value of the electric stress between two unequal spherical electrodes. The experiments carried out by F. W. Peek (Journal Am. Inst. of Electrical Engineers, 1911) for the General Electric Company of America prove conclusively the value in practical work of a knowledge of how to compute the maximum value of the electric stress between high-pressure conductors. With equal spherical electrodes the electric stress between them can easily be computed from known tables. When, however, they are unequal the calculation becomes so laborious that it is prohibitive to nearly every experimenter. The author develops formulæ for this case, by means of which, and of the formulæ for the capacity coefficients given in a recent paper to the society, the calculation is very appreciably shortened. When the distance between the spheres is very small compared with the diameter of either, the following approximate formula for $R_{max.}$ (the maximum value of the electric stress) can be used

$$R_{max.}=(V/x)[1+(2b-a)x/(3ab)+\{4(a-b)^2+ab\}x^2/45a^2b^2)].$$

where V is the maximum P.D. between the electrodes, x their distance apart, a the radius of the smaller and b the radius of the larger sphere. In this case a knowledge of the values of the capacity coefficients is not required.—F. J. **Harlow**: The cubical expansion of fused silica. The author describes experiments in which measurements of the cubical coefficient of expansion of fused silica from 0° C. to 100° C., and from 0° C. to 184° C., were made by the weight thermometer method. The values obtained were ${}_0S_{100}=99\cdot8\times10^{-8}$ and ${}_0S_{184}=144\cdot7\times10^{-8}$. The fundamental coefficient is considerably less than that calculated from previous linear measurements, whereas ${}_0S_{184}$ is only slightly less. A low value of the fundamental coefficient is to be expected, since the coefficient has been shown to change sign at about $-80°$ C. Observations of the ice-point before and after heating showed that no permanent charge in the volume of the bulb occurred through heating, thus confirming the utility of fused silica for thermometric purposes.—B. W. **Clack**: The temperature coefficient of diffusion. The paper describes further experiments carried out by the author with an improved form of the apparatus previously described (Proc. Ph. Soc., xxi., p. 374), by means of which the value of the coefficient of diffusion of salts through water can be found at various temperatures. Special flasks, similar to those already employed, were filled with the solution under investigation, and one was suspended from each arm of the balance in a large bath of distilled water maintained at constant temperatures in a thermostat room. The diffusion tubes of both flasks were of equal length, but their cross-sections differed considerably, and a method of differential weighing was used to compensate for any small changes in temperature. From the rate at which the flasks change in weight the value of the coefficient of diffusion of the salts is deduced. Figures are given for this value in the case of KCl and KNO_3 at various concentrations and at different temperatures, and from these figures the temperature coefficient of diffusion is found.—E. **Marsden** and T. **Barratt**: The α particles emitted by the active deposits of thorium and actinium. In a previous paper (Proc. Phys. Soc., August) the authors showed that if α particles are

counted on a zinc sulphide screen at a mean rate of μ per second, then the probability of occurrence of a time interval, of length between t and $t+\delta t$, is $\mu e^{-\mu t}$. This formula may be applied to test whether two α particles are given off simultaneously from a disintegrating atom or whether in any source of α particles there exist two successive α-ray products, the latter being of short life. In the previous paper uranium and polonium were shown not to give such irregularities, and in the present paper the same result has been found for actinium and thorium active deposits, although experiments of various investigators pointed to the probability of positive results. The experiments further suggest a lateral disintegration in thorium active deposit, and this is proved to be the case by results, which show that the two α-ray products in Thor. Act. Dep. (Th. C_1 and C_2) do not give an equal number of α particles when the active deposit is in equilibrium which is required by the ordinary disintegration theory. Thus it is concluded that of the atoms Th. C, 35 per cent. give rise to α particles of 4·8 cm. range and 65 per cent. to α particles of 8·5 cm. range, with probably the intermediate emission of β particles. Various cognate questions are also discussed in the paper.—S. W. J. **Smith**, W. **White**, and S. G. **Barker**: The magnetic transition temperature of cementite. The temperature at which cementite (carbide of iron) loses its ferromagnetism is determined sufficiently accurately for purposes of thermo magnetic analysis, and examples are given to show the possibility of using the thermomagnetic properties of cementite to determine whether that substance is present in any iron-carbon alloy.

MANCHESTER.

Literary and Philosophical Society. November 28.—Prof. F. E. Weiss in the chair.—Dr. J. N. **Pring** and D. M. **Fairlie**: The synthesis of hydrocarbons and their stability at high temperatures and pressures. The reaction between carbon and hydrogen, which has been found to produce methane at all temperatures up to 1600°, has been examined at various pressures up to 200 atmospheres. In this way it has been possible to evaluate and verify the equilibrium in the formation of methane, arising according to the equation $C+2H_2 \rightleftarrows CH_4$. In accordance with this reaction it follows from the law of mass action that $\frac{pCH_4}{p(H_2)^2}=K$, a constant at any given temperature. This was found to be the case in these experiments when any particular form of carbon was used. The yield of methane was found to increase with the pressure to the extent demanded by the above formula. At atmospheric pressure the equilibrium value with graphite corresponds to 0·24 per cent. at 1200° and 0·06 per cent. at 1575°. Values which were considerably higher were obtained with amorphous carbon, viz. an equilibrium which corresponds to 0·38 per cent. at 1200° and 0·18 per cent. at 1550°. This divergence is due to the fact that amorphous carbon is unstable at these temperatures, and gives temporarily "false" or "metastable" equilibria, which are higher than the true values. The great inertness of methane to decomposition enables this false equilibrium value to persist for some time. The velocity of the reaction between carbon and hydrogen is very much increased at high pressures. No other saturated hydrocarbon is formed or can exist at temperatures above 1100°, and at pressures up to 200 atmospheres. The heat evolved in the transformation of carbon into graphite can be calculated from the data obtained in this work by means of certain deductions of van 't Hoff. The results show that this heat of transformation increases in the range of temperature between 1100° and 1600°. It follows from this, in accordance with the law of Kirchhoff, that the specific heat of carbon increases more rapidly and is higher than that of graphite at these temperatures, whereas the reverse would follow from the accepted values of Kuntz and of Weber, which do not therefore apply at high temperatures.

DUBLIN.

Royal Dublin Society. November 28.—Prof. T. Johnson in the chair.—Sir Howard **Grubb**: Improvements in equatorial telescope mountings. The paper is divided into two parts, one dealing with the anti-friction arrangements of the large equatorials which are at present in course of construction for Johannesburg, Santiago de Chile, and Madrid. This first portion of the paper describes the newly designed apparatus, and reports upon the result of the first trials. The apparatus described is a development of that used in Sir Howard Grubb's large instruments, improved in many ways and adapted for use with the modern ball or cylinder bearings, which have been found to give very satisfactory results. The second portion of the paper deals with a new arrangement for a differential hour circle. There are two designs described, one of which has been suggested by Sir David Gill, and is being adapted to the Johannesburg and Santiago telescopes. In this arrangement the differential hour circle is kept continually moving by a series of electric contacts from the sidereal clock of the observatory. The other form which has been designed by the author of the paper has been adapted to the Madrid equatorial, and in this case the differential hour circle is kept moving *backwards* as respects the polar axis by a small piece of clockwork carried on the axis itself, and this enables actual right ascensions to be read off by this circle from a fixed vernier.—Prof. T. **Johnson**: *Forbesia cancellata*, gen. et sp. nov. This fossil plant was collected by the Geological Survey of Ireland in 1851 from the Lower Carboniferous of co. Cork, and named in 1864 by W. H. Baily "Sphenopteris, sp." The fossil shows marked dichotomy in all its parts, even in the ultimate pinnule segmentation. There is no sign of vascular tissue, but axis and frond are alike honeycombed. The chambers are lined with rows of parenchymatous cells and their septa, apparently strengthened by sclerotic bands connected with submarginal vertical striæ. One specimen shows signs of a fruiting condition comparable with that in Cephalopteris, Nathorst, from the Upper Devonian of Bear Island. On the assumption that Forbesia is evascular, the author considers it to be the most primitive of the *primofilices* yet found. Comparison with *Sphenopteris devonica*, Unger and Richter, is made.

BOOKS RECEIVED.

Traum und Traumdeutung als Medizinisch-Naturwissenschaftliches Problem im Mittelalter. By Dr. P. Diepgen. Pp. 43. (Berlin: J. Springer.) 1.20 marks.

Traité complet d'analyse chimique appliquée aux essais industrielles. By Profs. J. Post and B. Neumann. Deux. édition française by G. Chenu and M. Pellet. Tome troisième—premier fascicule. Pp. 468. (Paris: A. Hermann & Fils.) 15 francs.

Traité de Physique. By Prof. O. D. Chwolson. Ouvrage traduit sur les éditions russe et allemande, E. Davaux. Deux. édition française. Tome premier, by E. Cosserat and F. Cosserat. Pp. xviii+515. (Paris: A. Hermann & Fils.) 17 francs.

NOTES OF A NATURALIST.

Convergence in Evolution. By Dr. A. Willey, F.R.S. Pp. xiv+177. (London: John Murray, 1911.) Price 7*s.* 6*d.* net.

DR. WILLEY has had great opportunities of studying animal life under varied conditions, and he has given us in this interesting little volume some of the fruits of his observations. Here, in brief compass, will be found a zoologist's notes—field-notes and laboratory-notes—on points which have specially attracted him. Indeed, we think that some title suggesting that the book contained the varied observations of a zoologist would have been preferable to that which has been chosen. The book has been carefully edited and is well and clearly printed. One very conspicuous slip has, however, escaped notice, the reference to p. 90 instead of to 94 on the frontispiece itself.

The author tells us in the preface that he uses "the word convergence in a wide sense, embracing habits, functions, structures, and physiognomy." The sense is indeed so wide that the force of the term becomes attenuated. Thus even the convenient Box-and-Cox sleeping arrangements of the fruit-eating bats and crows in the maritime districts of Ceylon are classed as an instance "of convergent homing, the same trees affording hospitality in regular succession to day-flying birds and night-flying mammals" (p. 25).

Speaking of the well-known Kallima butterflies, the ordinary representation of the attitude is corrected, and it is shown that, at least in the Ceylon species (*K. philarchus*), the insect rests head downwards—a fact which has also been recorded of the Indian *K. inachis*. Concerning "the extreme amount of individual variation in the markings on the under side of wings, simulating all degrees of decay and discoloration and fungus attack" (p. 58), the author speaks with somewhat unnecessary respect of the notion

"that the constant repetition of such considerable variations as are met with in leaf-like Lepidoptera and Orthoptera, from generation to generation, is a standing witness against the truth of 'Darwinism,' inasmuch as, according to the Darwinian theory, such variations ought either to become fixed by natural selection or swamped by interbreeding" (p. 61).

The tentative suggestion on p. 61, "it may be that natural selection is interested in keeping alive the variations for the benefit of the species, not for the production of new species," may be accepted with some confidence when such polymorphic forms are looked at as a whole. If it be an advantage in the struggle for existence to resemble a dead leaf or another butterfly of a distasteful group, it is clearly a still greater advantage to resemble two or more kinds of dead leaf, or two or more unpalatable "models." It must be remembered that Kallima is by no means remarkable in this respect, for such polymorphism is well known in immense numbers of both procryptic and mimetic species.

It is satisfactory to find that such an extreme supporter of the far-reaching influence of convergence does not, at any rate for the present, assail the Darwinian conclusion that the same specific form is never repeated a second time as the outcome of an independent line of evolution.

"The present state of our knowledge," he writes on p. 138, "justifies the provisional assertion that the higher combination which leads to the establishment of an animal form possessing the essential component elements of a definite morphological type, cannot be repeated. The theory of convergence is therefore not calculated to precipitate us into morphological chaos, howsoever startling its manifestations may be."

The author is certainly prepared to be startling, as, for instance, in his conclusion that the closed nephridia as a whole, flame-cells (or solenocytes) and all, arose independently in the Polychæte worms and in Amphioxus. But before adopting any such hypothesis, it is prudent to investigate the evidence that these structures were present in the probable common ancestor of both Amphioxus and Polychæta. That such nephridia did thus exist in the primitive stock is strongly supported by their occurrence in several other groups which are much nearer to the common ancestor than either Amphioxus or the Polychæta. We have reason to believe that E. S. Goodrich, who originally discovered the resemblance in minute detail between the solenocytes of these two forms, considers that his conclusions have been much strengthened by the results of investigations on other groups of the Cœlomata.

There can be no doubt, however, that the independent origin of elaborate structures has occurred again and again. There is scarcely a subject in which it is more necessary to bear in mind the commonplace saying that every case must be argued on its merits without any bias in favour of one interpretation rather than another.

An excellent example of convergence in a structure of considerable complexity was brought forward more than thirty years ago by Fritz Müller. At the same time, we must remember that the male scent-organs on the wings of butterflies, to which he was referring, are constructed of modified scales—elements which are so excessively variable in size, form, and structure that the independent appearance of anything that can be produced by a scale is probably easier than almost any other feat of convergent evolution. Speaking of the scent-organs on the wings of certain male Satyrine and Nymphaline butterflies, Fritz Müller wrote:—

"I know of no other case which proves so clearly and irrefragably, and attests with such force, the truth of a principle which should never be lost sight of in morphological studies. When in two species certain organs which serve the same function are found in the same place, are composed of the same parts, occupying the same relative positions, and exhibiting similar forms—all this by itself constitutes no sufficient proof that these organs are homologous, nor does it afford the grounds for including the two species in the same family." [1]

CHEMISTRY OF FLOUR.

The Technology of Bread-making, including the Chemistry and Analytical and Practical Testing of Wheat, Flour, and other Materials Employed in Bread-making and Confectionery. By Wm. Jago and Wm. C. Jago. Pp. viii+908. (London: Simpkin, Marshall and Co., Ltd., 1911.) Price 21s. net.

THIS, the second, edition of a well-known work has been increased greatly, both in bulk and price, over its predecessors. Mr. Jago has had the cooperation of his son in its preparation.

It is far from easy to review at all adequately a book of 893 pages, and undoubtedly the work would have been of greater value if it had been materially condensed. Like most similar technological works, it commences with a good deal of pure chemistry, which is partly of very elementary character; very nearly all this could have been omitted with advantage.

The new edition contains most of the previous issue in its original form, but supplemented very fully by the additions required to bring it up to date. Whilst this has been done in a most painstaking and satisfactory manner, the practice is a mistaken one, if a really good book is to be produced, however much it may be justified by commercial reasons. As a result, the treatment is unequal; it would be unjust, however, to base any general criticism on these sections.

The usual plan adopted by the authors is to give a full abstract of all scientific papers in any way bearing on their subject. These are ordered, as a rule, in historical sequence, occasionally with the annoying result that, after a paper has been mastered by the reader, he finds the results controverted by the next paper. It is difficult in consequence to make out the authors' own views in places or to take a clear line as to the current opinions on a controversial question. The authors' own researches are interpolated at considerable length, and, though always valuable, their insertion sometimes tends to confuse the reader seeking for definite conclusions rather than the minutiæ of experimental detail.

The chemistry of bread and flour is far from being in such a chaotic state as this work would lead us to believe; it should have been possible to give a precise account of the present position and to indicate the controversial points, leaving the discussion of these at length to separate chapters.

Apart from these defects the book is most complete, and Mr. Jago is at his best in dealing with the more technical side of the question. Such chapters as those on the composition of wheat, the strength, composition, and bleaching of flour are full of valuable information. Mr. Jago, it is interesting to note, cannot agree with the so-called food reformers in their condemnation of our present bread supply, and the evidence he quotes shows that he is supported in this view by all the authorities of repute in this and other countries. The chapters on bread-making, wheat, flour, and bread "improvers" and on the nutritive value of bread, give a complete summary of all that is known at present on these questions.

The subjects of bakehouse design and the machine bakery and its management will appeal specially to those actually engaged in the trade—a baker, seeking to modernise his equipment, will gain the very best value for his outlay by studying them here.

The commercial testing of wheats and flours constitutes a very important section of the work: the subject is a difficult one, and much of the knowledge of it is still regarded as a trade secret. The difficulty chiefly lies in translating the results of the chemical tests into facts. There is much rivalry between the respective merits of the "chemical" and "baking" tests on flour; as Mr. Jago points out, "though baking is after all the final test of flour," chemical analysis is often able, not only to point out a departure from the normal, but, what is more important, to discover the cause. Millers and bakers have been slow as yet to follow the lead of the brewing industry and introduce a chemist into the works, but where this has been done there is abundant evidence that the laboratory work has proved an actual necessity for the maintenance of a uniform product of high quality. A very flattering testimony to this effect from the Ogilvie Flour Mills Co. is quoted in the book. The authors give of their best in this chapter, the pages describing the tests made with the aid of the tintometer being of especial interest as affording a means of measuring some of the subtle changes which take place in flour on storage, and giving more than a clue to their causes.

The more purely analytical chapters which conclude the book are in some respects less successful, some of the methods described being antiquated and untrustworthy. None the less, the section is a useful one to bakers' chemists, who will appreciate also the pages devoted to the testing of confectioners' raw materials.

Perhaps the most striking thought after a perusal of the book is how much of the present knowledge of the chemistry of wheat and flour is due to the work of the last few years, particularly to investigations instituted by those only remotely connected with the subject, and performed without thought of pecuniary reward. Additional satisfaction is derived from the consideration that the advance has been mainly made in this country, or by workers in Canada and the United States.

In conclusion, the authors may be congratulated on the result of their labours; they have compiled a dictionary which leaves nothing to be desired in the fulness of its material, and they have earned the gratitude of all future workers in the field.

E. F. A.

THE COLLOIDAL STATE.

Gedenkboek aangeboden aan J. M. van Bemmelen, 1830–1910. Pp. xxix+416. (Helder: C. de Boer, 1910.)

FIFTEEN years ago the number of those investigating the colloidal state would scarcely have reached double figures, and in the text-books of the period the subject received curt dismissal in a few paragraphs. Had it not been for the connection between colloids and dialysis it would have escaped

mention altogether. The general position of the science was but little advanced beyond where Graham in especial, and others, such as Frankenheim, Lüdwig, Cloetta, and Payen, had left it half a century earlier. Outside Prof. van Bemmelen's work a few scattered papers, mainly on the precipitating power of salts, or on the imbibition of water by organic jellies, made up the literature of the period. Biologists as a class seemed to have forgotten even the name colloid.

The sixty-two original papers gathered into the volume before us is eloquent testimony to the change which has taken place. The colloidal state has become the vogue, and any departure from simple linear relationship in the equilibrium between states of matter is in danger of being called colloidal—subclass adsorption—and so receiving summary and satisfactory explanation.

The historical position is, however, strictly logical, as indeed it must be if it is, in fact, a development of ideas. In the 'fifties and 'sixties of last century much work and speculation were devoted to the colloidal state; Frankenheim's forgotten paper of 1850, for instance, deserves to rank with Graham's masterwork. But the movement soon spent itself for lack of foundations to build upon.

The present era begins in 1873 with the appearance of the remarkable synthesis which van der Waals effected between the Laplace-Young theory of self-attractive matter, purely statical in character, and the doctrines of molecular kinematics as Clausius especially had developed them; and in 1875, with the equally remarkable extension of the theory of energy to include chemical potential which was made by Willard Gibbs. These, together with van 't Hoff's extension of the gas laws to solutes and Arrhenius's conception of electrolytic dissociation, opened the way for a great mass of work on the equilibrium between different states and different kinds of matter which expanded molecular physics into what is now called physical chemistry. This movement in turn has largely spent itself, unfortunately before it has given us a trustworthy specification of the distribution of energy in the fluid and solid states, and the study of the equilibria of matter in mass has, in one direction, been largely replaced by the study of heterogeneous systems in which one at least of the states is not present in mass at all, for this is the distinctive feature of what is called the colloidal state.

The papers in the memorial volume are forcible evidence of the multitude of problems connected with the colloidal state. Surface energy, the condensation of matter on to interfaces, osmotic pressure and dialysis, the physical state of soils, colloids in geology, viscosity, precipitation, and contact potential all are dealt with. The subject-matter of the paper by M. Duhem, which opens the series, must have been peculiarly grateful to van Bemmelen, for it is a protest against the application of thermodynamics to colloids on the assumption that they are multiphase systems. Twelve years ago the writer of this notice received from Prof. van Bemmelen a long letter of protest against any attempt to apply the phase rule to colloids, and the protest was in the main just. Equally favourable must have been his reception of Malfitano's protest against certain arbitrary distinctions which have become current, chiefly the distinction between chemical combination and adsorption. The distinction may have to be made, but it needs more subtle treatment than it usually receives.

Van Bemmelen's first work on colloids was his paper of 1877 on the absorptive property of soil, his last the paper, "Die Absorption, X.," of 1909. He was nearly fifty, an age when many cease active research, before he began his life-work. As van Bemmelen was led to colloids by his study of soils, it is but fitting that the volume should contain an important group of papers on colloids of the soil and in geology. Rohland, Hissink, Leopold, van Baren, Ehrenberg and Pick, Holwerda and Hudig write on these subjects. M. le Chatelier deals with the mechanical properties of mixtures of solid and liquid in a paper which is remarkable in that it makes no mention of Osborne Reynolds's work.

It is not possible to accord even the briefest notice to all, and contributions by Pappada, Tamman, Barus, Jordis, Freundlich, Spring, Svendburg, Bredig, Ringer, Schreinemakers, Lorentz, and others must be passed by with the remark that, as many of them will not appear in print elsewhere, the volume must be consulted by all workers on colloids.

His eightieth birthday saw van Bemmelen stricken with what proved to be his last illness. His modest soul was, above all whom the writer has known, superior to the need of praise. Thirty years' patient labour in a neglected field of science proves this. Yet one likes to think that so abundant testimony to regard and esteem brought joy and courage in those last hours.

W. B. HARDY.

THE ANALYSIS OF DYES AND DYED MATERIALS.

Identification of the Commercial Dyestuffs: being vol. iii. of a Method for the Identification of Pure Organic Compounds by a Systematic Analytical Procedure based on Physical Properties and Chemical Reactions. By Prof. S. P. Mulliken. Pp. vi+274. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 21s. net.

THE identification of natural or artificial dyestuffs either as such or in association with textile fibres, colour lakes, paper, food, or other articles, is a problem which at the present day presents many difficulties. Twenty or thirty years ago the number of dyestuffs was so small that their identification by an expert was a simple enough matter, but the enormously greater number of artificial dyestuffs now in use and the rapid rate at which this number is daily augmented, has not only greatly increased the difficulty, but also the need of trustworthy means of analysis. The dyer with many hundreds of dyestuffs now at his command is able to match any particular shade in a variety of different ways, but since the fastness for the purpose in view depends entirely upon a suitable choice of colouring matters, it becomes particularly important that in matching an approved pattern it should be possible not only to reproduce the shade, but also to

select the same or similar dyestuffs. It is also a desideratum for the merchant or textile manufacturer to be able to ascertain whether the colour of the materials dyed for him is always obtained with the dyestuffs specified, whether the shade dyed by one firm is or is not a chemical match for that dyed by another, and other similar questions. The analytical chemist is also frequently called upon to determine the actual dyestuff or dyestuffs employed, for example, in the composition of a lake pigment for wall-papers or lithographic printing, or to identify the material used for colouring certain food products.

With the large number of dyestuffs which come into consideration it is obvious that no satisfactory scheme of identification can be based upon individual and empirical reactions, such, for instance, as the changes of colour produced by caustic soda or concentrated sulphuric acid. Such individual tests can only be employed effectively after the genetic relationships of the dyestuff in question have been ascertained by means of suitable group reagents; and only those chemical properties can be employed as group reactions which depend upon general differences in chemical structure. Another reason why such a principle can alone prove satisfactory is that the scheme adopted must be capable of including and referring to their appropriate groups the new colouring matters which are constantly appearing, the individual reactions of which are unknown.

In the analytical scheme published by A. G. Green in 1893, which is based in part upon the earlier schemes of Witt and Weingaertner, the chief differentiation is effected by the behaviour of the dyestuff upon reduction with zinc dust, and the reaction of its reduction products with air and with chromic acid. Whilst nitro-, nitroso-, and azo-compounds are completely broken down upon reduction, and cannot therefore be reoxidised, those dyestuffs which may be regarded as having an *ortho*-quinonoid structure give leuco-compounds which are readily reoxidised to the original dyestuff by air, and those to which a *para*-quinonoid structure is attributable give leuco-compounds stable to air but reoxidised by chromic acid. Still, a further group are not reducible at all, whilst dyestuffs of the anthracene class are converted into coloured hydro-derivatives.

In 1905 and 1907, Green, assisted by Yeoman, Jones, Haley, and Stephens, published a very complete scheme for the analysis of dyestuffs upon textile fibres, in which the above principles were employed in conjunction with other group tests. In this scheme sodium hydrosulphite was substituted for zinc dust as the reducing agent, and the colourless potassium persulphate for chromic acid, all the reactions being effected upon the fibre instead of in solution. This scheme of analysis is not only applicable to dyed materials, but can also be readily applied to colouring matters in the solid form or when associated with mineral bases, food products, &c., by previously transferring the dyestuff to wool or cotton.

In the work under review the author claims to have produced a perfected scheme of analysis of general applicability. In place of employing group reactions to differentiate the dyestuffs according to their structural relationships and dyeing properties, the system adopted is largely empirical, being based upon the exact determination of colour changes effected by various reagents, the shades obtained being compared with standard shade cards and the results tabulated by a system of lettering. Although Green's reduction and oxidation tests are also employed as "generic" reactions, their indications are interpreted in a strictly formal manner under arbitrary but rigidly fixed conditions. This produces the result that the main groups or "genera" frequently contain dyestuffs which are entirely unrelated. We find, for instance, azo-colours of the benzopurpurine type classified together with rhodamine (a pyrone colour); phosphine and other acridine colours classified with annatto; auramine (a diphenylmethane derivative) in association with primuline (a compound of the thiazol class); various alizarine colours in close conjunction with rose Bengal and violamines (pyrone colours); and dyes of the azo-class, triphenylmethanes, and natural red woods amongst the azines, oxazines, and thiazines. The author's system also involves the coordination of dyestuffs of entirely different dyeing properties, irrespective of whether they are "basic," "acid," "substantive," or "mordant" colours.

The book contains colour reactions of some 1475 individual dyestuffs, which are recorded with extreme precision for the selected conditions. Although, however, it has involved much careful labour, the utility of the work has been largely sacrificed to the desire to obtain an impossible degree of accuracy and through the unscientific and inconvenient system of differentiation adopted. Such a rigid system of colour reactions does not take account of the fact that commercial dyestuffs usually contain variable impurities or are shaded with small quantities of other colouring matters. Furthermore, it may be questioned whether the exact tint obtained in the tests would not be also affected by small indeterminate factors, such as the purity of the reagents or the quality of the textile materials used in dyeing. Lastly, the scheme could not be applied to mixtures without a complete separation into the constituents, a condition which is seldom possible.

ARTHUR G. GREEN.

MUNICIPAL ENGINEERING.

A Manual of Civil Engineering Practice: Specially arranged for the Use of Municipal and County Engineers. By F. Noel Taylor. Pp. xii+809. (London: C. Griffin and Co., Ltd., 1911.) Price 25*s*. net.

THIS book has been written to supply the needs of young engineers who propose to devote themselves to those branches of engineering practice which fall to the lot of the municipal and county engineer, or the borough surveyor; the duties which have to be undertaken by such officials are of a most varied character, and involve a wide range of knowledge; books of reference are essential to such men, and Mr. Taylor, drawing largely upon his own professional experience, has dealt with the entire field of work covered by the term "municipal civil engineering."

The first six chapters are devoted to surveying and levelling, and the mensuration of earthworks, the subject being treated with special reference to the class of work which has to be carried out by municipal engineers, such as the laying out of roads, tram-lines, sewers, &c.; next follow three chapters dealing with such general problems as the stresses and strains in beams and struts under given loading, and the methods of determining the necessary scantlings of simple beams and pillars. In a special chapter on the various materials employed in constructional work, the author gives a concise description of their structure, essential properties, manufacture, and the usual methods of testing them to ensure soundness and freedom from all defects. Retaining walls and their design are fully discussed in chapter xvi., and examples are worked out to illustrate the use of the formulæ and the methods of securing safety with economy of material.

The making and repair of roads form a very important part of the duty of a municipal engineer: prior to the advent of the motor-car, the roads outside town areas had been much neglected, and they were in a totally inadequate condition to deal with fast and heavy traffic; as a consequence the questions of road maintenance and road construction have entered during the past ten years upon an entirely new phase. To mention only one of the changed conditions, with horse traffic the dust nuisance was, in country districts, a matter of slight importance; at the present day, on roads on which there is a heavy motor-car traffic, the suppression of dust becomes a factor which must be dealt with, and to which other details may have to be subordinated. In chapter xix. the author gives an excellent abstract of a report upon the proceedings of the International Road Congress, which met in Paris in 1908, prepared for the Local Government Board of Ireland by the chief engineer, Mr. Cowan. This congress agreed to a series of resolutions embodying the views of the delegates as to the lines upon which in the future roads should be constructed and maintained, and also as to how best to cope with the dust problem, though at present opinion is divided as to the respective merits of surface tarring and tar-macadam.

A valuable chapter is that devoted to the design of structures in reinforced concrete; some excellent notes are given as to the essential qualities of the two materials employed—the concrete and the steel—then a series of simple formulæ is worked out, and, finally, typical illustrations of design are given, such as floors, piles, reservoir walls, bridges, and sewers, in each case attention being directed to practical difficulties which have to be met and overcome, if thoroughly sound, durable work is to be produced. This chapter is appropriately followed by one on masonry road bridges and similar work.

The problem of the removal of domestic and trade refuse, solid and liquid, is dealt with in six very complete chapters—one of the best sections, in fact, of the book. All the most modern and efficient methods are discussed and explained, both in regard to the laying out and the construction of sewers, and in regard to the ultimate treatment of the sewage at the outfall works. An abstract is given of the report of the Royal Commission on Sewage Disposal of 1908, a report which embodies the views of chemists, biologists, and engineers, and is a storehouse of information upon a subject which is of vital importance to the general public, and the layman is as much concerned with the efficient solution of this knotty problem as the engineers who have to design and maintain the necessary works. To make this section of the book complete, the author has added a chapter on the ventilation of buildings and house drainage, in which the best types of modern sanitary house fittings are described, with the help of a series of good illustrations.

Waterworks, their design and maintenance, form the subject of three chapters. Full details are given of the best system of filtration, of methods of softening hard waters so as to render them more suitable for domestic purposes, and of detecting and checking waste of water, a constant source of worry to the engineer in charge of such works; some figures are given to show how excessive this waste by leakage and by the culpable negligence of householders may be, and how important it is to put a stop to it, if needless expense in constructional works is to be avoided, and a shortage of supply in periods of drought prevented.

Constructional steel work is discussed in a very complete chapter. The examples chosen cover a wide range of such class of work—overhead water tanks, roofs, and bridges of various type. The illustrations in this chapter are clear and not overburdened with detail, and are, therefore, much more likely to prove useful to a designer who consults them than is often the case with plates reproducing engineering drawings. For the guidance of young engineers, Mr. Taylor has given a special chapter to the subject of the preparation and drafting of specifications, a chapter which will no doubt be constantly consulted, as it is full of the most useful hints and advice.

Mr. Taylor is to be congratulated on the production of a book which will find a place on the desk and in the drawing office of every civil engineer, and the publishers, too, must be given a word of praise for the excellence of the numerous plates and wood-cuts.

T. H. B.

CHEMICAL PHENOMENA OF LIFE.

Chemical Phenomena in Life. By Prof. F. Czapek. Pp. ix+152. (Harper's Library of Living Thought.) (London and New York: Harper and Bros., 1911.) Price 2s. 6d. net.

MESSRS. HARPER could not have secured a more authoritative or a clearer writer than Prof. Czapek, of Prague, to present to the public the most recent views of biochemistry. The chemistry of protoplasm and its behaviour, as well as that of its constituents, have been greatly illuminated since that branch of chemistry known as the chemistry of colloids has been subjected to investigation. The main properties of colloids were discovered by Thomas Graham in 1861, and the conception of ions we owe to Faraday. Nevertheless, the science of physical

chemistry remained in a dormant condition until van 't Hoff and Le Bel, twenty-one years ago, laid down the famous law named after them, and put forward their views on the nature of solutions. Exact and even mathematical researches in this region were thus rendered possible, and physical chemistry since then has grown at a prodigious rate, and has increased the boundaries of knowledge, not only so far as chemistry and physics are concerned, but also in the biological field as well.

Unfortunately the growth of a new science means the introduction of a new language, and those who write in it are not always able to realise that it is unintelligible even to those who have received a scientific training a few years previously. Such a book as Prof. Czapek's is therefore a godsend, for it explains in the clearest manner the new language as well as the new facts. Although the author is a professor of plant physiology, he treats his subject in a wide manner, so as to be helpful to animal physiologists as well. The properties of colloids, the use of the ultra-microscope, the significance of the protoplasmic membrane, the velocity of reactions, catalysis and the enzymes, and the general laws of immunity are among the subjects treated in somewhat less than 150 small pages. Each page is rich with information and full of thoughtful and pregnant suggestions.

Prof. Czapek concludes that, so far as chemical and physical phenomena are concerned, our knowledge is now sufficiently advanced for us to be quite sure that it is unnecessary to call in the assistance of any mysterious "vital force" in order to explain the activities of protoplasm. The filling in of the still numerous gaps are mostly the working out of points of detail, and that is only a matter of time.

"There is only one part of physiology which is not yet accessible to our methods, and which we cannot prove to be ruled by the well-known laws of inanimate nature. These are the psychological phenomena."

When we remember that less than a century ago organic chemistry was regarded as equally inaccessible to experimental methods, there is some hope that in the future even psychological phenomena may yield their secrets to the investigator. W. D. H.

OUR BOOK SHELF.

Where Do We Come From? Is Darwin Correct? A Philosophical and Critical Study of Darwin's Theory of "Natural Selection." By Herbert Morse. Pp. iv+344. (London: Kegan Paul and Co., Ltd., 1911.) Price 7*s.* 6*d.* net.

HAVING read many of the eulogistic articles on Darwin's work which appeared at the time of his centenary, Mr. Morse was prompted to look into the matter for himself. He does not claim for his work any higher authority than that to be granted to the opinion of the man in the street. "Anyone who can read and write, who has the ordinary powers of reasoning, and is possessed of some knowledge of the nature and value of evidence, is as capable of passing as sound an opinion on the value of the theory, that, that evidence endeavours to corroborate as any scientist of them all."

Let us give a few quotations to illustrate the competence and temper of this new philosophical critic. "Man is a self-improving organism, no other organism is. Every other organism is the mere sport of nature, at the mercy of environment, a mere physical puppet." The struggle for existence "was the great promoter and agent of variation." This, which is stated as one of Darwin's fundamental propositions, reveals an abyss of misunderstanding. We are treated, as usual, to the old chestnut: "If these new creations were all similar at the outset, it seems inconceivable that any period of time, however prodigious, or any set of circumstances, however extravagant, could by any process of slow accretion have converted, say, a flea into a flamingo."

The author is therefore led to suppose that there were many independently originating primitive organisms. He appears to believe that a theory of polyphyletic evolution is quite anti-Darwinian, and he brings back old times by dividing the animal kingdom into four classes. There have been many stern critics of Darwinism who have done service to evolution-theory, advancing it a little beyond the stage at which Darwin left it, but these have been men careful to understand what Darwin meant, careful not to credit him with conclusions he did not hold, careful to acquaint themselves with the facts of the case. We cannot rank Mr. Morse among these.

The World's Minerals. By Leonard J. Spencer. Pp. xi+212+40 coloured plates. (London and Edinburgh: W. and R. Chambers, Ltd., 1911.) Price 5*s.*

AT first sight one gains the impression that this is merely a remarkably cheap picture-book, published in time to be handy as a Christmas gift. The forty coloured plates exhibit an Oriental splendour and a daring which does not hesitate to represent the play of colours of labradorite and precious opal, or even the metallic lustre of native gold and silver. These dazzling pictures, prepared under Dr. Hans Lenk, of Erlangen, are themselves worth the price of the book, which, however, is far more than a mere album of German chromo-lithographs. For the editor of *The Mineralogical Magazine* has written descriptive text around the pictures, and has preceded this by an excellent introduction to the study of minerals, which makes the book something more than a pretty volume for collectors of pretty stones. Thus in only twenty-two pages the author manages to give a clear and wonderfully comprehensive survey of the difficult subject of crystallography, not even omitting to deal with Miller's notation.

On p. 16 the choice of 2 for the axial ratio of a dimetric crystal is unfortunate, suggesting as it does a simplicity comparable to that of indices, dealt with in the same paragraph. A figure like the 1·771 of anatase would have avoided any such implication. On p. 20 the drawings of rhombohedra are apparently printed upside down, and the hexagonal prism is not satisfactory. These are, however, minor points, and the fact that one can find no worse faults in what amounts to a text-book of systematic mineralogy comprised in the first forty pages, on the forms, physical characters, chemical composition, and classification of minerals, speaks well for the value and accuracy of the work. R. F. G.

The Rubber-Planter's Notebook. By Frank Braham. Pp. viii+108. (London: Crosby Lockwood and Son, 1911.) Price 2*s.* 6*d.* net.

THIS book is what it purports to be, a handy book of reference on Para rubber planting, with hints on the maintenance of health in the tropics and other general information of utility to the rubber planter. It is well written, and the condensed information contained in

it, so far as it goes, is well selected and in the main correct.

Many a "creeper" and new hand on Eastern estates and elsewhere will owe Mr. Frank Braham a debt of gratitude for this handy little volume, which doubtless is the nucleus of a future work of more extended scope, not one with large type on art paper, but a planter's "Molesworth," of use to the old hand as well as to the beginner.

The author's section on general information will be found specially useful, and his essential rules for the preservation of health in tropical climates are admirable if intended for the young planter going out to the East for the first time; but for the older resident in the tropics "drink as little as possible—fluids inflate the bowel" is dangerous advice. The ingestion of a sufficient quantity of water or other bland liquid is essential if for no other reason than to counterbalance the effects of excessive perspiration. In hot weather the kidneys are very largely relieved of their excretory duties by the skin. If then the individual for years has been in the habit of still further relieving them by drinking as little as possible, it is not astonishing that in cases of emergency they are unable to return to their normal state of efficiency, and if blackwater fever is encountered death in such cases may be the result.

In these essential rules also mention of the all-important hot bath and change at sundown would have added to their completeness. The book, however, should command a ready sale.

Die moderne graphische Reproduktion. Ein Führer und Ratgeber durch das Gebiet des Illustrationswesens unter Berücksichtigung der für die Wiedergabe bestimmten Originale. Gemeinverständlich dargestellt von L. P. Mosler. Pp. vi+52+xiv plates. (Jena: Gustav Fischer, 1911.) Price 2 marks.

IN this booklet the author gives a concise description of the methods of illustration as at present practised, so that those who desire to avail themselves of such methods may have some idea of their characteristics and possibilities, and be guided as to their choice. He refers also, shortly, to methods of making drawings and photographs for reproduction. Following the text are fourteen plates. Nine of these are impressions from half-tone blocks made from the same original to show the effect of the fineness of the screen, a reproduction of a reproduction, a "duplex" print, &c. There are also a four-colour print, a collotype, and a photogravure.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Distastefulness of *Anosia plexippus*.

REFERRING to the interesting note on "The Distastefulness of *Anosia plexippus*" in NATURE of October 12, I should like to suggest that the experiment, though interesting in itself, does not materially strengthen the case for the usefulness of mimicry. To make a good case for mimicry in the sense in which that term is ordinarily used, the mimic *Basilarchia archippus* should be tested and found palatable. Further, if mimicry means anything at all with reference to these two species, North American birds should eat some butterflies but not molest *Basilarchia archippus*. So far as observations have been reported, American birds eat butterflies *very* rarely, and there is no evidence, so far as I know, either from direct observation or from the thousands of stomach-content examinations made by the United States Department of Agriculture, that its non-mimetic relatives are eaten more often than *Basilarchia archippus*.

If European birds show the same indifference towards butterflies as is manifested by North American birds, either the "model," *Anosia plexippus*, or the mimic, *Basilarchia archippus*, might with impunity become widely disseminated in Europe. A. M. BANTA.

Cold Spring Harbor, N.Y., November 20.

I HAVE a shrewd suspicion that if the result of my experiments upon *Anosia plexippus* had proved this butterfly to be highly palatable, the dwindling minority of mimicry sceptics would have made the very most of the fact, and claimed that it "materially strengthened the case" against Bates's theory of mimetic resemblances; and in this they would have been perfectly right, so far, at all events, as the particular instance is concerned. But since the experiments proved the precise opposite, those who believe in the theory may reasonably maintain that the case for the usefulness of the mimicry to *Basilarchia archippus* is thereby materially strengthened. It appears to me that few more important items of evidence in favour of the theory of mimicry can be established than demonstration of the distastefulness of "models."

Again, I think Mr. Banta overrates the negative evidence he cites in support of the view that birds seldom prey upon butterflies under natural conditions. My opinion to the contrary is based upon a large number of experiments made in the gardens of the Zoological Society of London, and published in the Proceedings of the society for September. I can recollect no exception to the rule that insectivorous birds were roused to attention at once by the sight of butterflies, their keenness suggesting very forcibly that they knew them, either by instinct or by experience, to be part of their natural diet.

Not less strongly suggestive was the determination with which they pursued, and the precision with which they generally caught, the butterflies on the wing when let loose in the shelterless aviary. Conversely, the skill evinced by the butterflies in dodging their pursuers in mid air was one of the most striking features of the experiments. Just as one is compelled to believe that the instinctive doubling of the coursed hare when overtaken by greyhounds indicates the habitual method of escape of the species from fleet-footed foes, so must one believe that the evasive twist of a butterfly when pursued by a bird is an inherited habit that has proved a means of salvation to members of that species in the past when chased by similar enemies. If, as is maintained, birds do not under natural conditions prey upon butterflies to a sufficient extent to be reckoned as serious enemies, what explanation is to be offered of the marked reaction observable between the two sets of animals when pitted against one another? R. I. POCOCK.

Zoological Society, December 6.

The Weather of 1911.

I HAVE studied with great care and interest Dr. Shaw's letter in NATURE of November 30 disclosing a promising field of inquiry into the causes of such abnormalities of weather as we have, for example, experienced during the summer and first half of the autumn of the present year. Seizing hold of the very fact Dr. Shaw's letter refers to, which has apparently induced him to look in the direction of the upper atmosphere above 9 kilometres for new lines of investigation, namely, that certain types of distribution of barometric pressure, normally rainy, occasioned little or no rainfall in the summer of 1911, I had before reading his letter entertained the idea that somehow or other the persistent, parching drought might have been due to an abnormally reduced *absolute* humidity of the atmosphere (at least of those strata not immediately in contact with surface water supplies) over these islands, so much reduced that the convection currents adequate to produce rain in more normal conditions failed to do so in the present year. I admit, of course, that a decreased absolute humidity of the air in hot summer weather, with the ocean all round us, would be a very different thing to account for, and perhaps could only be brought about by a persistent flow

of the air currents to our region from some arid continental region like the interior of Asia, which would be very unlikely in summer.

But the suggestions embodied in Dr. Shaw's communication no longer render necessary such an assumption as small vapour-content of the air to account for the circumstances of the drought. For I take it that if a barometric depression were transmitted to the surface strata entirely by variations of pressure occurring beyond the convection region at a height of about 9 kilometres, there would not be engendered the powerful rain-producing convection currents usually associated with cyclonic circulation when a barometric depression takes its origin wholly or partly in causes residing in the lower layers themselves.

Should this proposition not follow on the lines indicated in Dr. Shaw's letter, I should be glad if he would correct it. L. C. W. BONACINA.

Hampstead, N.W., December 2.

MR. BONACINA would draw a distinction between barometric depressions transmitted from above and those which take their origin wholly or partly in causes residing in the lower layers themselves, and he would attribute a peculiarly rainy character to the latter. I know of no facts which enable us to draw with certainty the distinction in individual cases, and I should have been glad if Mr. Bonacina had cited some examples which were demonstrably of the second type. I cannot speak very positively on the subject. There is a certain hyperbolic region, sometimes shown on weather maps, between a pair of cyclones and alternating anticyclones where I think such depressions may occur. The weather associations of that particular distribution are peculiar; in the words of a well-known verse:

> When it is good, it is very very good,
> But when it is bad it is horrid.

In summer, thunderstorms with copious rainfall may occur with such a distribution. They are associated with areas of shallow depression—local secondaries—which may be entirely surface-bred; but the pressure differences involved are so slight that they must be regarded as belonging rather to the embroidery than to the outlines of the pressure distribution of the globe.

Let me take the opportunity to add that the further study of the physics of rainfall might contribute to the clearing up of some misconceptions about its meteorological significance. Suppose that we regard rainfall as incidental to convection, that is, to the process of righting instability in the lower or middle layers of the atmosphere, which may be caused by the superposition of layers of inverted density. Consider the effect of variations of pressure imposed entirely from above. If the lower layers contain a stratum of floating cloud, it follows from the difference of adiabatic temperature-change in cloudy and dry air that compression will produce instability at the lower surface of the cloud and rarefaction will produce instability at the upper surface. Alternate compression and rarefaction, such as would be imposed from above if some giant were playing upon the middle and lower layers of the atmosphere, with their cloud strata, like a concertina, would give alternating instability of different types. With one type rain would be produced. What would happen with the other I have not fully made out; perhaps the mammato-cumulus cloud may illustrate it. A good deal depends upon the vertical temperature gradient, of the causes of which at present we know little.

Certainly if there were no cloud layer to form a locus of instability, compression would simply raise the temperature of the air, and hence its potential dryness. The other stroke of the concertina, the rarefaction, might itself produce cloud, possibly at more than one level, and its continuance would maintain the cloud and the instability necessary for continuous, but fluctuating, rainfall if supplies of suitable air were forthcoming. We have here an explanation of cloud layers at different levels and of the well-known tendency towards cloud and rainfall with a falling barometer that is satisfactorily independent of surface conditions. Looking into the details, we can also see that a falling barometer alone is not necessarily a sufficient cause.

Parenthetically, may I express the hope that Mr. Bonacina or some other student of weather will refer to the figures for the dryness of the air of the past summer as compared with air under similar conditions of wind direction, &c., in previous summers? The facts are available and well worth investigation. There is, I have reason to think, a high negative correlation between humidity at 9 a.m. and the duration of sunshine for the day, and this may point to another factor in the cause of the brilliant summer.

I hope Mr. Dines will make good his view that the distribution of temperature in the upper layers is not related to the direction of the air currents. When I wrote I had in mind particularly a cold invasion in the upper air of July 29, 1908, with a northerly wind, and the apparent increase in intensity of the phenomena of a line squall at higher levels. But if we can be assured that cold invasions begin at the bottom, it will free us from much difficulty.

In the interesting letter from Dr. Carl Ramsauer published in your issue of December 14 the argument is based upon the assumption that during the past summer condensation in the atmosphere was inhibited for want of nuclei. The assumption requires proof before it can be accepted as a basis of physical reasoning. Supersaturation of air in the free atmosphere is often assumed, but, so far as I know, it has never been demonstrated, and meteorologists, as a rule, do not feel themselves at liberty to use it. W. N. SHAW.

December 19.

THE contributions in your columns to this subject are of great interest. I will venture, with your permission, to propound one or two questions suggested by the letter of Dr. Carl Ramsauer. On his hypothesis, would it not follow that all periods of minimum solar activity would be marked by weather of the 1911 type? Is this the case?

On the same assumption, it would seem to follow that the same type of weather would extend over the whole earth: has this been the case? We have, I think, heard of torrential rains in northern Italy in the beginning of summer, and of the early onset of winter in Canada.

Again, assuming this hypothesis, not the earth only, but all the planets would have been affected. Have the supposed snow-caps of Mars shown any shrinkage?

Failand, December 15. EDW. FRY.

The Photography of Hα during Solar Eclipses.

IN NATURE for December 7 (p. 182) the report of the council of the Royal Society is said to state that at the total solar eclipse of April 28 the observers sent out by the Joint Permanent Eclipse Expedition secured observations with a short-focus prismatic camera showing the whole of the hydrogen series, with the additional remark that "this is the first time Hα has been photographed at an eclipse."

In the interest of accurate annotation, however, this statement of the council must be modified, as reference to the reports presented to the Royal Society of the eclipse of 1893 (West Africa) and 1898 (Viziadrug) will show that the Hα line was recorded as a strong line on the photographs obtained with prismatic cameras at both these eclipses by the expeditions from the Solar Physics Observatory. It was also recorded by other observers at the Indian eclipse of 1898. CHARLES P. BUTLER.

The Nematodes of the Thames.

REFERRING to my former communication on this subject, I am happy to say that I have at last discovered the host of at least one of the species of nematode found in the Thames. Mr. Chas. Todd, of Tottenham, has kindly sent me a sample of mud from near the Tower Bridge containing vast numbers of Tubificidæ. Among these are *Limnodrilus hoffmeisteri*, *Tubifex campanulatus*, and other interesting fresh- or brackish-water worms. The nematode has so far been found only in Tubifex. It gains an entrance into the spermathecæ, where it develops to the great inconvenience of its host. HILDERIC FRIEND.

Swadlincote.

MICROSCOPE STANDS.

CONSIDERABLE attention is now being directed by those interested in microscopy to various questions connected with the build of the instrument irrespective of the purely optical parts. We have thought it desirable, therefore, to ask the opinions of those with large experience in the designing and production of stands both here and on the Continent. These opinions are given below.

CLAIM FOR SUPERIORITY FOR THE ENGLISH STAND.

By the term "English microscope" is meant the distinctive type of instrument which has been built to embody conveniences for working with modern high-class objectives and condensers, which conveniences cannot be found in combination in any other microscopes than those of British origin. Among them are the following:—(1) *The tripod foot; (2) *a long range of coarse adjustment for the use of low-power objectives; (3) *the body tube fitted with mechanical draw tube to allow for the adjustment of objectives for thickness of cover-glass; (4) the mechanical stage scientifically constructed as a part of the whole instrument; (5) the compound substage with rackwork to focus and screws to render the substage condenser axial with any objective that may be in use; (6) *fine adjustment to substage; (7) *the Wenham binocular body; (8) the various fittings for substage apparatus, eyepieces, and objectives of the Royal Microscopical Society's standard gauge; (9) *all the working parts fitted with sprung bearings and controlling screws so that compensation for wear and tear may be readily effected.

In the English microscope alone are all these conveniences to be found in combination. In isolated instances one or two of the fittings are included in microscopes of foreign origin, but none are provided with those marked with an asterisk, in the manner that is usual in the English instrument.

Numerous microscopes are made in Great Britain which are not of the typical English model, designed for students and special uses, but even in these it is customary to incorporate some of the qualities and conveniences enumerated above, and they permit of greater latitude in individual working on the part of the intelligent user than is possible with a microscope which must of necessity be used as a tool that magnifies on account of its limitations.

The English microscope has never suffered from want of appreciation on the part of those who have had leisure or taken sufficient interest to use its many refinements, and it is significant that it is the prevailing type that is employed by the thousands of amateur workers throughout the world to-day.

To the professional worker it has not appealed in the same degree, but gradually he is appreciating the fact that to do the best he must have the many facilities that the English microscope affords, and it is in consequence gradually displacing instruments of simpler construction.

The English microscope has always been of substantial proportions, but a definite advance in its precision took place when between twenty and thirty years ago it was recognised by the leading exponents of microscopy, and especially Dr. Dallinger and Mr. E. M. Nelson, that the improved optical means then introduced could not be advantageously employed without adequate mechanical conveniences. A slower acting fine adjustment suitable to the increased numerical aperture of objectives was the earliest step, and after many years' insistence that the now almost extinct direct-acting fine adjustment was sufficient for all requirements, the Continental makers fell into line with the English makers.

Then followed the mechanical draw tube, and only those who have seen the beautiful manipulative effects obtained by leading workers, can realise what can be done by its use in correcting for slightly different thicknesses of cover-glass. It has been stated that a difference of draw-tube length of 5 mm. is of no practical importance, but this is not the experience of the modern worker. His critical effects are obtained within closer limits.

Improvements were simultaneously introduced into the general design of microscopes, refinements which advanced workers found desirable were incorporated, and British manufacturers produced instruments which are to this day known by the name of the microscopist who provided the specification.

The result has been that the English microscope is a distinctive one, and is unlike its contemporaries of other countries in several important features.

The mechanical stage of the English microscope, built as part of the instrument, has very forcibly revealed its advantages in connection with the recent introduction of immersion paraboloids and reflecting condensers. The attachable mechanical stage of the Continent carries the object slip along the surface of the stage. For these immersion paraboloids it is essential that the under-side of the object slip shall be in contact, by means of immersion oil, with the top lens of the paraboloid. It will be obvious that as the mechanical screws carry the object slip along the surface of the stage the oil from the under-side of the object slip will pass on to the stage surface. The immersion oil is thus drawn away and the contact is no longer maintained. The same effect is produced with any immersion condenser, so that in effect the attachable form of mechanical stage largely interferes with the proper working of any condenser or paraboloid which may be of the immersion type.

It should be borne in mind in this connection that the Abbe illuminator, if used in its full efficiency, must be immersed. This fact is generally overlooked, and it is exceedingly rare for an Abbe illuminator to have its maximum numerical aperture developed by means of oil immersion.

The English mechanical stage has each plate working independently, and the object is carried in a fixed position on the top moving plate. The oil therefore does not run on to the stage surface as in the pattern just mentioned.

The compound substage is typically English. The necessity for centring screws to enable the optical centre of the substage condenser to be adjusted to the objectives in use has to this day not been recognised by Continental opticians.

A fine adjustment to the substage was the accompaniment to the more general use of the oil-immersion condenser, the absolute focussing that this required being realised better by this means than by coarse adjustment only.

There is still want of conformity with the Royal Microscopical Society's substage size on the part of non-British makers, and the condensers are not interchangeable without alteration.

The advantages associated with the tripod foot which, properly proportioned, is light in weight, and yet imparts rigidity which is not possessed by any other shape, the convenience of being able to use low-power objectives, and the Wenham's binocular body with its exquisite stereoscopic effects, and, finally, the obviously better construction from a mechanical point of view of fittings that are adjustable in consequence of wear, all unite to make the British microscope an instrument of precision.

It is admitted that many of the refinements which are referred to here are of but small use to the man who does not make himself acquainted with elementary principles of microscopical theory and manipulation; but any worker who intends to wrest from his instrument the best it is capable of yielding and desires to make himself proficient in its use will find that the English microscope must be employed.

A Defence of the Continental Form.

The Continental microscopes are of a shorter build than the original English pattern, and are normally supplied with a tube length of 160 mm. (6 inches), while the English tube length normally supplied is 250 mm. (10 inches).

The short Continental microscopes are more convenient to use on a table of normal height, and, owing to their compactness and portability, are mostly used in laboratories of universities, institutions, &c., in this country.

The equipment of these microscopes varies considerably, and the better microscopes of the leading makers are fitted with all the modern appliances demanded with an up-to-date fully equipped microscope.

The stands are often fitted with mechanical stages of exquisite design and large opening, being revolvable, and having a displacement for the cross motion large enough to allow for searching over an entire slide; they are very convenient if serial slides are to be examined. Verniers are provided to locate the exact position of the object, thus saving a great deal of time in finding the exact spot noted on any previous day.

The substage arrangement is of the usual Abbe form, with sliding sleeve to receive either a fixed ordinary Abbe condenser or an achromatic condenser with centring device.

The iris diaphragm carrier on the substage is of a very ingenious construction, being provided with rackwork to place the iris out of centre, up to a range to meet the extreme margin of a numerical aperture of 1·40, and, owing to the iris diaphragm carried being revolvable around the optical axis of the microscope, specimens can be illuminated from any azimuth and obliquity with the greatest ease.

The recess in the iris diaphragm carrier takes a polariser, also mica films, in a convenient manner should the microscope be used with polarised light.

The complete substage with condenser is provided with a rack and pinion work, and the best make acts with such precision, having no back-lash whatsoever in the rack and pinion movement, that the fine adjustment of the substage is absolutely superfluous.

The horseshoe foot, provided with three resting points on the extremity of the horseshoe, has been much improved of late in order to ensure great firmness of the stand for visual observation. For horizontal use, as is the case in photomicrography, the Continental models are chiefly used with a suitably prepared sole plate with levelling screws and clamping device; this mode has also proved to be of great service even with the larger tripod stands of best English make.

The body tube of some of the Continental stands are exceptionally wide in order to allow the use of low-power objectives without cutting down the field, and also to avoid internal reflection.

The fine adjustment is placed near the stage in the most convenient position, and is of the greatest sensitiveness, an interval on the scale representing a movement of 2/1000 of a millimetre. The rackwork is sufficiently large to meet even low powers of 4-inch focus.

All important sliding parts are not sprung but carefully ground in and free from back-lash, which is essential if the microscope is expected to remain in focus, chiefly with high powers. Sprung motions, however carefully done, are bound to counteract.

First-class Continental makers do not spare expense in making these carefully ground-in sliding parts, and this is the best and surest manner to guarantee a first-class microscope to be steady in focus. With the cheaper Continental models the sprung sliding sytem is used to some extent, but less accuracy in this motion is required with such microscopes, which are chiefly designed for low powers.

For binocular vision, even with oil-immersion lenses, the Abbe stereoscopic eyepiece of latest form is simply unique.

To sum up the advantage of the Continental model, it is only fair to say that the instruments, though simple in construction, are certainly most efficient for the highest class of research work in microscopy.

English and Continental Microscopes.

The average English microscope of the present day is a representation of a simplified instrument of what in former days presented a complicated and massive piece of mechanism. The Continental model, on the other hand, has gradually been evolved from an exceedingly simple design to an efficient and practical instrument better adapted to the requirements of the serious worker than is the typical English model possessing the multiplicity of racks and screws and milled heads so much admired by a certain class of dilettanti. The serious worker in science has not the time to play with the large variety of unnecessary fittings embodied in the typical English microscope, while the dilettante finds a whole day may be well spent in a variety of manipulations effecting mechanical and optical adjustments (mainly mechanical) to enable him to examine only a few objects, and such a day's work often proves to be more exhausting physically than mentally.

The tripod base is more rigid than the typical Continental "horseshoe" base, but of recent years the leading Continental makers have so modified the "horseshoe" in that the "toes" are spread outwards and the "heel" prolonged to an extent that the instrument is sufficiently rigid for all practical purposes. When using the microscope in the horizontal position for photomicrography the tripod base gives greater rigidity when not fixed by screws or clamps to the photographic apparatus, but it is not wise to employ the microscope in photomicrographic work without having it securely clamped to the base plate of the apparatus, and therefore in this respect the Continental "horseshoe" is equal to the English tripod.

There are Continental microscopes made with "horseshoes" giving equal rigidity in vertical and horizontal positions to the tripod, and possessing the great advantage of free access to the substage, a feature generally lacking in the typical English model.

The substage with centring arrangement is rarely met with in Continental models, but instead, centring adjustment is provided in the nosepiece, which is undoubtedly a more accurate method of obtaining optical alignment than by displacing the condenser to suit a change of objective. Indeed in photomicrography the absence of centring screws in the substage means a considerable saving of time and greater accuracy is obtained by employing centring screws, or the Continental objective sliders, attached to the body tube of the microscope.

As regards the stage: at one period the principal difference existing between the two makes was that the Continental was provided with an attachment giving mechanical motion, while the English mechan-

ical stage formed an integral part of the instrument. Now we find a "built in" mechanical stage in the best Continental microscopes, and they, as instruments of precision, are of a higher order than is obtained in the English models.

The fine adjustments in the Continental models are made in a variety of patterns, but in their best form we have as yet nothing in this country to compare in quality of mechanism and slowness of motion.

The mechanical draw-tube is provided in only a few Continental models, a feature more common in the English. Instead of this adjustment the Continental makers provide the objective with correction collars to allow of adjustment for varying thicknesses in cover glasses, and this is considered more accurate than the mechanical draw-tube.

It is often claimed by English makers that one of the advantages in possessing an English microscope is that certain fittings are made to the Royal Microscopical Society's standard measurements. As regards objectives and eyepieces there is little or no difficulty in getting the products of all reputable makers interchangeable, whether English or foreign; but a different state of affairs prevails in respect to substage sleeves, for it is generally found that not only does one English maker's condenser refuse to fit into the substage of another, but it is a common fault to find substage sleeves of English microscopes varying so much in diameter that the ideal of R.M.S. standardisation has yet to be reached.

Neither the society nor the makers have met the needs of English microscopists in this respect, so it may be left to the National Physical Laboratory to step in and fill the gap, which is a wide one.

Sprung fittings is another feature claimed for certain English models, yet a curious contrast is shown respecting the durability of these adjustments as compared with the Continental.

The screwdriver is a tool frequently used by owners of the former class of instrument, while the leading Continental instruments require adjustments only once in many years of daily usage.

Accordingly it would appear that fewer sprung fittings add to the durability of the instrument.

When choosing a microscope to embody the greatest possible facilities for the present-day needs of the serious worker, it will be found to be a product of one of the best German houses.

SLEEPING SICKNESS AND BIG GAME.

IN spite of the fact that a commission has been sent out to Nyasaland to investigate the problem of the relations of the big game to the spread of sleeping sickness, under the direction of Sir David Bruce, the most eminent authority on this subject in this or any other country, persistent efforts continue to be made to force the Colonial Office to prejudge the issue and to cause the game to be exterminated before its relation to the disease has been determined accurately. The latest of these efforts was made in the House of Commons on December 13, by Dr. Chapple, member for Stirlingshire, who urged the Secretary for the Colonies to relax the severity of the game laws so as "to permit of the natives hunting *game known to harbour the trypanosome in their blood* in order that both the *game and the infecting fly which invariably accompanied it* might be driven off from the populous centres." We have italicised two statements in Dr. Chapple's speech, as reported in *The Times* of December 14, in order to direct attention to points in which scientific knowledge at the present time does not confirm, or is at variance with, the grounds on which he bases his plea for extermination. His argument is but another instance of the lamentable ignorance of our legislators in scientific matters.

The question under consideration has been discussed at some length in the last three numbers of NATURE, and it will be sufficient here to summarise briefly the present position of the problem. The extermination of the game is urged by its advocates on the following grounds:—(1) That antelopes and other wild animals harbour *Trypanosoma gambiense* in their blood, and are therefore dangerous as a source of infection; (2) that the tsetse-flies instrumental in the transmission of sleeping sickness are dependent upon, and accompany, the big game, and would disappear if the game were destroyed.

With regard to the first point, it has never yet been shown that the big game, in a natural state, harbours the trypanosome in its blood, but only that antelopes can be infected with *T. gambiense* in the laboratory; and this has been shown also for *practically all the common domestic animals*. It may be left to common sense to judge whether, in a region in which the tsetse-flies abound, the domestic animals surrounding the villages and homesteads, or the shy and timid antelopes keeping their distance in the jungles, are likely to be the greater danger to human beings as a source of infection.

With regard to the second point, those who are acquainted with the tsetse-fly in its native haunts are by no means agreed that it is dependent on big game, or that it necessarily accompanies it; on the contrary, many instances have been adduced of tsetse-flies swarming in places where there is no big game of any kind. If, however, it were admitted for the sake of argument that the flies follow the big game, what effect is likely to be produced by the destruction of their natural food? Is it to be supposed that the flies would sit down and die helplessly of starvation? Is it not far more likely that they would be attracted by the food supply offered by the domestic animals surrounding the homesteads, animals which almost without exception are potential hosts of the trypanosome just as much as the big game? If such an effect were produced, the danger to human life might be increased tenfold.

The whole question is one beset with dangers and difficulties, calling for full investigation of the complex factors of the case and for the utmost caution before proceeding to take action. To carry out the extermination of the game in the present state of our knowledge would be simply a leap in the dark, an experiment which, so far as can be foreseen, would lead to no amelioration of the conditions, but might, on the contrary, be fraught with disastrous results. The Colonial Secretary must be commended for having refused, so far, to allow his hand to be forced in the matter. The wisest course in the circumstances is surely to "wait and see" what are the conclusions reached by Sir David Bruce's Commission.

EXPLORATION IN THE DEPARTMENT OF PETEN, GUATEMALA.[1]

THE ruins of Tikal, completely hidden in the forest in the northern part of Guatemala, distant about thirty miles from the Lake of Peten, and forty miles from the nearest habitation, are among the most important and interesting in Central America.

Since my second visit to these ruins in 1882, I have been anxiously awaiting the result of further explorations on this attractive site, and at last it has come in a handsome volume published by the Peabody

[1] Memoirs of the Peabody Museum of American Archæology and Ethnology, Harvard University. Vol. v., Nos. 1 and 2:—"Explorations in the Department of Peten, Guatemala: Tikal," by Teobert Maler; "Preliminary Study of the Ruins of Tikal, Guatemala," by A. M. Tozzer. Pp. 135+28 plates+2 maps. (Cambridge, U.S.A.: The Museum, 1911.)

Museum of Harvard University, under the auspices of which the explorations were undertaken. The first and

FIG. 1.—View from Temple No. 1 looking west.

second of these expeditions were conducted by that veteran explorer, Mr. Teobert Maler, and the third by one of the most prominent of the younger generation of Americanists, Dr. Alfred M. Tozzer. Owing to some unfortunate friction between Mr. Maler and the Peabody Museum, Mr. Maler's plan of the ruins and some of the detail plans of the buildings he describes were not obtained for this volume, and it is therefore difficult to do full justice to his share of the work.

During Mr. Maler's preliminary expedition (1895) he remained only eight days at the ruins. On his next expedition (1904) he was camped there for four months, from August to November. As these are the rainy months, he certainly avoided the great difficulty attending a residence at Tikal during the dry season, which is the scarcity of water; on the other hand, four months' camping in a tropical forest during the rains must have entailed great hardship, and it must often have been very difficult to carry on any work at all.

It is to be regretted that Dr. Tozzer's report is not accompanied, as is Mr. Maler's, by a personal narrative; moreover, he gives no indication of the length of his stay at the ruins. Personal narrative may be of no particular scientific interest to the archæologist, but it is of the greatest value to future explorers to know what difficulties have to be overcome and how much work can be accomplished within a specified time.

Mr. Maler discovered a considerable number of hitherto unknown sculptured stelæ, and both his report and Dr. Tozzer's are furnished with many detailed plans of buildings.

Dr. Tozzer was accompanied by Mr. Merwin, who observed the azimuths of the front and back walls of the five principal temples with a transit instrument, but the sketch plan printed in this volume does not show the buildings plotted according to these bearings, and although it shows much that was previously unrecorded, a more accurate survey of the site is to be desired; in fact, although the work accomplished by Mr. Maler and Dr. Tozzer adds considerably to our knowledge, much yet remains to be done at Tikal.

Dr. Tozzer does not say whether he made paper squeezes of the carvings and inscriptions, but it is to be hoped that moulds were made, for, excellent as Mr. Maler's photographs are, photographs alone do not suffice for a careful study of the carving, and plaster casts are absolutely necessary.

Mr. Maler says that Tikal covered an area of four to five kilometres square, but surely this requires verification by further measurements. Dr. Tozzer's sketch map, which includes all the buildings described in the reports, measures less than $1 \times 1\frac{1}{4}$ kilometres. Isolated buildings may be found at a distance of two kilometres from the centre of the city, but this does

FIG. 2.—Circular Stone Altar at Tikal.

not prove that the city proper covered such a great area as Mr. Maler states.

To those who have not studied American archæology, it is a surprise to learn that the remains of a city covering nearly a square mile, with five great stone-built temples, raised on pyramidal foundations, the highest reaching an elevation of nearly two hundred feet from the ground, as well as many smaller temples of similar form, and well-built stone houses containing numerous small, stone-roofed chambers, are to be found hidden away in the depths of a tropical forest in America. However, American archæology is still in its infancy, and may have some strange developments in store for us; it is a vast field, and as the interest in it is rapidly increasing, there is every hope that the rising enthusiasm of students and explorers will result in dispelling much of the mist which obscures the curious civilisations, some of which developed and waned many hundreds of years before the first Spaniard set foot on the American continent. Mr. Maler probably closes a long career of exploration in the forests of Guatemala and Yucatan with his last journey to Tikal, but from Dr. Tozzer one can happily look for useful and conscientious work, both in the field and in the study for many years to come.

ALFRED P. MAUDSLAY.

THE ECOLOGY OF DESERT PLANTS.

IN a publication of the Carnegie Institution of Washington, entitled "The Water-Balance of Succulent Plants," Mrs. E. S. Spalding adds to the statistics that she had previously given concerning the reversible changes in dimensions and form of *Cereus giganteus*, the massive stem of which acts as an expanding and contracting water-reservoir. Her observations on the rate of growth of this "giant cactus" lead to the conclusion that it requires a hundred years to attain a height of ten metres. Mrs. Spalding shows that analogous reversible change in volume takes place in *Echinocactus Wisliz-e-ni*, and *Opuntia* spp., and gives the interesting information that the former, at first spherical in form, becomes irregularly columnar, lop-sided, and top-heavy, so that it readily topples over or is uprooted by the wind. She suggests that the inefficiency of the root-system thus revealed represents a case of incomplete adaptation, which accounts for the "sparse occurrence" of the plant.

FIG. 1.—*Cereus giganteus* having a dead trunk and living branches which bore flowers one year after the death of the trunk.

By the somewhat cryptic and certainly inelegant expression "water-balance," Mrs. Spalding and her co-author, Prof. D. T. Macdougal, mean the amount of water stored in the plant. The latter author's contribution to the work includes statistics as to the rate and amount of loss of water of certain succulent plants, including the three species mentioned above; for instance, he concludes that individuals of *Cereus giganteus* "12 to 20 metres in height would contain from 2000 to 3000 litres of water," and that "such individuals might lose from 1000 to 1600 litres of water . . . and still survive." As an excellent example of the power of endurance displayed by this species under net loss of water, Prof. Macdougal mentions that branches may remain alive and even bear flowers many months after the death of the main trunk. A number of successful photographs illustrate the work, and one of these is reproduced here.

SIR JOSEPH DALTON HOOKER, O.M., G.C.S.I., F.R.S.

THE most distinguished son of a very distinguished father, Joseph Dalton Hooker was born at Halesworth, in Suffolk, on June 30, 1817. Early in 1820 his father was appointed by the Crown to fill the chair of botany in the University of Glasgow, a post which he held until, in 1841, he became director of the Royal Gardens at Kew. As a consequence Hooker was educated in Glasgow, passing through the High School to the University, from which he obtained the degree of M.D. in 1839. Devoted as a lad to the reading of works of travel, we learn from Hooker himself that he was especially impressed by Turner's description of the Himalayan peak of Chumlari, and by the account of the Antarctic island of Kerguelen contained in Cook's voyages. An opportunity of investigating the latter came to him very early in his career. When he completed his medical studies, Hooker entered the Royal Navy as an assistant surgeon, and was gazetted to the *Erebus*, then about to start, along with the *Terror*, on the famous Antarctic expedition led by the eminent navigator Sir James Clark Ross. Throughout this expedition the young assistant surgeon held the post of botanist, and during its three years' cruise in the southern seas he was able to visit New Zealand, Australia, Tasmania, Kerguelen, Tierra del Fuego, and the Falkland Islands, amassing large collections and acquiring a vast amount of botanical information.

Shortly after the close of this expedition, Hooker, in 1843, became assistant to Graham, then professor of botany in the University of Edinburgh, and in 1845, when Graham was succeeded by the elder Balfour, Hooker was appointed botanist to the Geological Survey of Great Britain. Much of his time during this period was devoted to the preparation for publication of the results obtained during the course of his Antarctic voyages. But in 1847 this work was temporarily suspended, and his appointment on the Geological Survey was relinquished, in order that Hooker might add, by further travel, to his first-hand knowledge of the vegetation of sub-Antarctic and temperate regions, a corresponding acquaintance with the botany of tropical countries. The region selected was north-eastern India, then a practically unexplored tract. The undertaking, originally designed as a private enterprise, through a series of happy accidents received official recognition, and the expenses involved were to a partial extent met from public funds. Hooker left England in November, 1847, reaching India in January, 1848. After some three months spent in the Gangetic Plain and Behar, during which he ascended the sacred hill of Parasnath, Hooker made his way to the Himalayas, reaching Darjeeling in Sikkim in the middle of April. The next two years were devoted to the botanical exploration and topographical survey of the Himalayan state of Sikkim and of a number of the passes which lead from that

country into Tibet; if he did not actually reach he at least had opportunities of seeing the noble peak of Chumlari, which had helped to fire his youthful ambition to become a great traveller. Towards the close of the year 1848 Hooker had an opportunity, which has come to no one since, of crossing the western frontier of Sikkim and exploring a portion of eastern Nepal. During the greater part of the time spent in the eastern Himalayas, Hooker travelled and surveyed alone, but in October, 1849, he was joined by Dr. Campbell, the superintendent of Darjeeling, who had obtained official authority to visit Sikkim. Shortly after Campbell joined him, the Sikkim authorities seized the opportunity thus offered to imprison and maltreat Campbell, at the same time confining Hooker, whom, however, they refrained from injuring. The captives were released towards the end of December, 1849, and the next three months were spent by Hooker in arranging at Darjeeling his vast collections.

Early in 1847 Dr. Thomas Thomson, of the Indian Medical Service, son of a colleague of the elder Hooker in the University of Glasgow, and an old classmate and intimate friend of his own, had been deputed by Lord Hardinge to visit and report upon certain portions of the western Himalaya and Tibet. This mission completed, Thomson made his way to Darjeeling in order to join Hooker, and the year 1850 was devoted by the two friends to the botanical investigation of eastern Bengal, Chittagong, Silhet and the Khasia Hills.

On his return to England in 1851 Hooker resumed the task of publishing his Antarctic results, and began, in conjunction with Thomson, to elaborate those of the Indian journeys. The collaboration of the two friends in the preparation of a "Flora Indica," the first and only volume of which appeared in 1855, ceased when Thomson returned to India, and the appointment of Hooker in that year to the post of assistant director at Kew under his father brought with it duties more than adequate to occupy the time and attention of an ordinary official. The performance of these duties, however, did not impede his Antarctic studies, and in 1860, which saw the completion of the great work on the botany of the Antarctic voyage, Hooker was able to add still further to his extensive knowledge of topographical botany. In the autumn of that year he was asked by Captain Washington, hydrographer of the Royal Navy, to take part in a scientific visit to Syria and Palestine. In the course of this journey he ascended Lebanon and investigated the history, position, and age of the cedar grove which has made that mountain a household word, but of which until then nothing was accurately known.

On the death of the venerable Sir William Jackson Hooker in 1865, Hooker was appointed director of the Royal Gardens, Kew, in succession to his father. This position he held during the next twenty years. The engrossing work and added responsibilities of this period did not, however, prevent Hooker from taking his full share of those public duties which naturally fall to the lot of men of his eminence. He presided over the thirty-eighth meeting of the British Association held at Norwich in 1868, and over the Department of Zoology and Botany in the Biological Section at the meeting held at Belfast in 1874. In 1873 he undertook the arduous duties of president of the Royal Society, and occupied the presidential chair for the next five years. Nor did these duties entirely debar him from further botanical travel. In 1871 he undertook, in company with the late Mr. Ball and Mr. G. Maw, a botanical expedition to Morocco and the Atlas range; in 1877, in company with his intimate friend, Dr. Asa Gray, and with Dr. Hayden, of the United States Survey, he took part in an important botanical journey to Colorado, Wyoming, Utah, the Rocky Mountains, the Sierra Nevada, and California.

From the time of his retirement in 1885, Hooker's life was spent at The Camp, near Sunningdale, where he had built for himself a home, the grounds of which, furnished with all the advantages that knowledge and taste can provide, contain one of the most interesting collections of plant forms in this country. Here he devoted himself with the energy and enthusiasm of one commencing his career to the completion of tasks already in hand and to the initiation of new ones. His critical acumen, which remained unaffected by advancing age, and his physical vigour, which became seriously impaired only a few weeks before his death, enabled him, in the freedom from administrative duties which retirement had brought, to accomplish work which as regards its amount must be considered the ample harvest of a lifetime, and as regards its quality, and no higher tribute could well be bestowed, fully sustained the reputation of his earlier publications.

The work which Hooker accomplished can be but briefly outlined here. Space forbids a complete enumeration of his many contributions to natural knowledge; all that can be done is to endeavour to indicate the various lines of his intellectual activity, and to note how these were affected by the leading events in his personal history. While still an undergraduate, Hooker had been at work in his father's herbarium in Glasgow. The earliest of his results appear in a paper on Indian mosses, written in collaboration with the late Prof. Harvey, which was published in 1840, shortly after he had joined the expedition under Ross. Work connected with cryptogamic plants was one of his strongest early inclinations, for some of the most important of his papers, prepared during the years 1844 to 1847, when he had returned from the Antarctic, deal with the hepatics, lichens, mosses, and algæ of the southern circumpolar regions. But a predilection for work on fossil botany manifested itself almost as early in his career; another early paper, written and published in 1842, while still botanist on the *Erebus*, deals with an examination of a Tasmanian fossil wood. As his general work on the Antarctic material he had accumulated made progress, we find, however, that his cryptogamic work came to be done more and more in collaboration with workers who had made some particular lower group their special province. The botanical results of the Antarctic voyage occupy six quarto volumes subdivided into three sections: (1) the "Flora Antarctica," completed in 1847, before he left for India; (2) the "Flora Novæ Zelandiæ," issued in 1853, after his return from the East; and (3) the "Flora Tasmaniæ," published in 1860, after he had become assistant director at Kew.

But the preparation of the first section of the Antarctic work did not impede his activities while connected with the Geological Survey between 1845 and 1847. Before undertaking the duties of the post he had already given attention to problems connected with fossil botany; while attached to the Survey he prepared during 1846–7 several important papers on the subject, the most notable of these being a discussion of the vegetation of the Carboniferous period as compared with that of the present day, which was printed in 1848. But his interest in the subject did not end with the severance of his connection with the Geological Department; two interesting papers on fossil botany from his pen were published in 1855. After his appointment as assistant director, however, he made no further formal contribution to knowledge in this particular field. His Antarctic work and his

duties in connection with the Geological Survey did not, however, suffice to occupy all his time prior to his departure for India. He drew up an "Enumeration of the Plants of the Galapagos Archipelago," issued in 1847, and collaborated with the late Mr. Bentham in preparing the "Flora Nigritiana," incorporated by Sir W. J. Hooker in the "Niger Flora," published in 1849.

Some of the results of Hooker's Indian observations, notably those relating to his journeys in the Indian plains, were published by the Asiatic Society of Bengal in 1848. But if on his return to England in 1851 he reverted with energy to the elaboration of his Antarctic results, the Indian material was not neglected. He began, in collaboration with Thomson, that "Flora Indica" the issue of which in 1855 has already been alluded to. In connection with this work two sumptuous illustrated folios were issued; the first, on "The Rhododendrons of the Sikkim-Himalaya," was edited from Hooker's notes, sketches, and material, by his father, between 1849 and 1851; the second, "Illustrations of Himalayan Plants," chiefly made for an Indian friend, Mr. Cathcart, in the Darjeeling neighbourhood, was edited, with descriptions by Hooker himself, in 1855.

This was, however, by no means all that he was able to accomplish. In addition to the families formally described in the solitary volume of their "Flora Indica," Hooker and Thomson discussed in the Linnean Society's Journal various problems of interest relating to individual Indian plants, and issued a series of papers, "Præcursores ad Floram Indicam," dealing more completely with a number of important natural families. Finally, Hooker's "Himalayan Journals," one of the most fascinating books of travel in our language, in which his Indian journeys are dealt with generally, was issued in two octavo volumes in 1854. Probably no botanical field work has proved more fertile in interest or provided material of greater value in the discussion of biological and phytogeographical problems than that done by Hooker. Yet great as were his botanical results and pardonable as it is in the botanical worker to look upon these as Hooker's highest achievement, it is doubtful whether the topographical results were not of even greater moment. These results, reduced by Hooker himself, with the assistance, as he tells us, of various Anglo-Indian friends who came under the magic spell of his personality, were arranged at Darjeeling during the early months of 1851. They formed the basis of a map, published by the Indian Trigonometrical Survey, with the aid of which, such is its accuracy and its detail, the operations of various campaigns and political missions have been carried to a successful issue.

The ten years during which Hooker was assistant director at Kew were marked by extraordinary activity. The time that could be spared from executive duties was far from being entirely absorbed in Antarctic and Indian work. In 1862, and again in 1864, he dealt with important collections of plants from Fernando Po and the Cameroons in papers valuable in themselves and in the evidence they afford that his interest in the flora of the Dark Continent, first evinced in 1847, had never abated. This interest showed itself once more in a paper of 1875, which may be mentioned out of sequence, on the subalpine vegetation of Kilimanjaro. In this case, however, the interest was associated with another which had guided much of his Antarctic study and had manifested itself in 1856 and in 1861 in dealing with the Arctic plants collected during the Franklin searches and the McClintock expedition. The problems involved were dealt with in a comprehensive fashion in 1861 in Hooker's classic, "Outlines of the Distribution of Arctic Plants." A group of kindred problems had presented themselves to Hooker when engaged in the study of the vegetation of the more outlying Antarctic and sub-Antarctic islands, and subsequently when dealing with the plants of Galapagos. To this period therefore we may most properly ascribe the formation of the views enunciated in a notable discourse on "Insular Floras," delivered at the meeting of the British Association at Norwich in 1866. Yet another allied group of problems called for consideration in connection with his Antarctic, Indian, and African studies; his conclusions with regard to these are stated in his "Introductory Essay to the Flora of Tasmania," published in 1860; the opinions there expressed on the origination and distribution of species suffice to explain the action which Hooker took when, in conjunction with Lyell, he had induced Darwin, in 1858, to publish a preliminary sketch of his famous hypothesis.

To the same period of his activities belongs the share taken by Hooker between 1858 and 1864 in the preparation of Thwaites's enumeration of the plants of Ceylon. To this period we owe, moreover, the codification of the results given in the second portion of the Antarctic flora in the form of a "Handbook of the New Zealand Flora," contributed to the series of Colonial floras published under Government authority. The work was issued in part in 1863; the concluding portion was published in 1867, shortly after the period had come to an end. But to this period we owe, in addition, various important special studies on the structure and affinities of Balanophoreæ, published in 1856; on the origin and development of the pitchers of Nepenthes, in 1859; and on *Welwitschia,* in 1863. The most obvious result of Hooker's visit to Syria in 1860 is a paper on the cedars of Lebanon, Taurus, Algeria, and India, published in 1862. In this article a subject of great interest and considerable difficulty is handled with masterly skill. But the journey bore further fruit in the form of a singularly pleasing sketch of the botany of Syria and Palestine, contributed in 1863 to "Smith's Bible Dictionary." Extensive and important as these various contributions to botanical knowledge are, they do not include all that Hooker accomplished while assistant director; the most onerous and important undertaking initiated during this period has still to be mentioned. In renewed collaboration with Mr. Bentham was commenced one of the outstanding botanical monuments of the nineteenth century, in the form of a great "Genera Plantarum"; of the three volumes which this work includes the first was completed in 1865.

Hooker's succession in that year to the directorship of Kew brought with it all the responsibilities connected with the administration of that national institution. These, however, did not prevent him from continuing to take his share in the preparation of the "Genera Plantarum," the second volume of which was completed in 1876, the third and concluding one in 1883. The directorship, however, brought with it the duties of continuing the *Botanical Magazine* and the *Icones Plantarum,* edited by his predecessor. These duties Hooker continued to fulfil even after his retirement in 1885; in the case of the *Icones* until 1889, in that of the *Magazine* until 1902, and with the collaboration of Mr. W. B. Hemsley for two years longer, his connection with this historic serial ending in 1904, with the completion of the one hundred and thirtieth volume. The death of his father imposed on Hooker yet another filial duty of the most arduous character, that of replacing in 1870, by his own "Student's Flora," the "British Flora" of his predecessor. In 1873 he annotated and rearranged the natural families of plants in an English version of the "Traité général" of Le Maout and Decaisne, and in 1876 he wrote for the series of science primers that on "Botany."

The results of Hooker's journeys in North Africa in 1871 are given in "A Journal of a Tour in Marocco and the Great Atlas," written in collaboration with Ball and published in 1873; those of his visit to North America in 1877 were summarised by himself in our pages (NATURE, vol. xvi., p. 539).

Of the addresses and discourses delivered by Hooker during this period that on "Insular Floras" of 1866 has already been alluded to. That delivered from the president's chair to the British Association in 1868, with its whole-hearted advocacy of an acceptance of the hypothesis of Mr. Darwin as the surest means of promoting natural knowledge, was perhaps more important in its effect on scientific thought generally. His British Association sectional address of 1874, on "The Carnivorous Habits of Plants," was an illuminating review of those problems to which his own observations and researches on Nepenthes in 1859 had directed attention.

It has recently been remarked that "so broad-based were the foundations of Kew as laid by Sir William Hooker that they have been but little extended by his followers. Their work has been to build a noble superstructure. Viewed in detail Kew is hardly anywhere the same as it was in 1865. But the framework is very much the same." These remarks are so just that no useful purpose could be served by any attempt to enumerate here the various manifestations of Hooker's activity as an administrator, or to detail the alterations and additions which marked his directorship. That activity, as was said in this journal by Prof. Asa Gray in the article on Hooker in our "Scientific Worthies" series (vol. xvi., p. 538), was exercised "in such wise as to win, along with national applause, the gratitude of the scientific world." Nor is more than a passing allusion due to a bitter controversy in 1872, Hooker's unsought share in which the world of science made its own. Those whose curiosity extends to the unedifying may find the details in a parliamentary paper; it is sufficient to remark that in the following session the Royal Society chose Hooker to preside over their councils.

We have yet to allude to what was the heaviest and the most prolonged task of Hooker's life, the publication of the "Flora of British India." During his collaboration with Thomson, prior to 1855, in the elaboration of the results of their Indian journeys, the two friends had been able to render available for scientific study the botanical treasures preserved in the East India House. The heavy but essential task of distributing these involved as a corollary the preparation and issue of a catalogue of the specimens dealt with. This catalogue Hooker was able to publish in 1865. A similar necessity subsequently arose in connection with the Peninsular Indian herbarium brought together by the late Dr. Wight. This subsidiary distribution was completed and the requisite ancillary catalogue was prepared by 1870. The task of preparing for British India a flora on the lines of those written at Kew on behalf of the various colonies could at last be undertaken. This task was at once begun; the opening part of the initial volume appeared in 1872 and the volume was completed in 1875. It was followed by the second volume, finished in 1879, by the third, finished in 1882, and by the fourth, the concluding part of which was issued, just as Hooker retired, in 1885.

Nearly half of the gigantic task had still to be accomplished, so that in Hooker's case retirement, if it brought relief from administrative cares, did not bring leisure. The heavy labour was faced without flinching; the progress of the work remained unchecked. The fifth volume, containing four parts, was completed in 1890; the sixth, also a volume of four parts, in 1894; the seventh and concluding volume appeared in 1897.

In the meantime, however, Hooker undertook a new and onerous task. Shortly before his death the late Mr. Darwin informed Hooker of his intention to devote a considerable sum to be expended in providing some work of utility to biological science, and to arrange that its completion be assured should this not be accomplished during his lifetime. The difficulties which he had experienced in his own studies led Darwin to suggest that this work might take the form of an index to the names, authorities, and countries of all flowering plants. At Darwin's request the direction and supervision of the work was undertaken by Hooker; the actual preparation was entrusted to Mr. B. D. Jackson. The result is the "Index Kewensis," of which the publication alone occupied the period from 1892 to 1895. During the period devoted to its preparation and publication the work received the unremitting care and attention of its director and its compiler. Other works, however valuable they may be, admit, as a rule, of some relative estimate. To the "Index Kewensis" no such mode of judgment is applicable; it is simply invaluable, and stands a lasting monument to the wisdom and generosity of Darwin, the piety and sagacity of Hooker, the care and fidelity of Jackson. While this "Index" was in progress, Hooker arranged for publication in 1895 a century of drawings of orchids, for which he provided descriptions, from among the manuscript figures placed at his disposal by the Calcutta herbarium in connection with his own work on the "Flora of British India." Scarcely had the responsibility attaching to the preparation of the "Index" been laid aside ere Hooker undertook, as an act of justice to the memory of a distinguished predecessor, to edit the "Journal of the Right Hon. Sir Joseph Banks, during Captain Cook's first voyage, 1768–71"; this work was published in 1896.

The time-consuming and exacting labour which the preparation of the Indian flora entailed had barely ended when the chivalrous generosity of Hooker was once more invoked. The late Dr. Trimen had undertaken the preparation of a "Handbook of the Flora of Ceylon." Three volumes of this work were issued between 1893 and 1895. While it was in progress Trimen was mortally stricken; the third volume was issued with the hand of death upon the author. When Trimen died the Government of Ceylon sought Hooker's aid. With indomitable courage the veteran of over eighty undertook the heavy task of completing the work of another author who had fallen a victim in the prime of life, under restrictions as to scope and style which, whether they met with his approval or not, were at any rate different from those hitherto observed by himself. Perhaps no more touching token of regard than this was ever paid to the memory of a friend. The fourth volume of the Ceylon flora, to some extent edited from material left by Trimen, appeared in 1898; the fifth and concluding volume, which it fell to Hooker to prepare himself, was issued in 1900. Still, as he himself once expressed it, "dragging the lengthening chain" of the *Botanical Magazine*, Hooker devoted the next two years of his own life to writing that of his father, which appeared in the "Annals of Botany" in December, 1902. Coincident with the appearance of this tribute of filial piety came the arrangement which relieved him of some of the pressure which the editing of the *Magazine* entailed, but not the anticipated freedom. At the request of the Government of India, Hooker undertook to prepare for the "Imperial Gazetteer" a sketch of the vegetation of the Indian Empire. This task, one of the most difficult, when regard is had to the limitation of space almost necessarily

imposed, that could well be undertaken, was successfully accomplished, and has resulted in an essay comparable with that on the botany of Syria and Palestine, written thirty years earlier.

The active intellect which had for five and sixty years taken a fierce delight in laborious days, and had throughout found a task to be more congenial in proportion to its difficulty, was not likely to seek satisfaction in an unbroken round of quiet breathing. If new worlds need not be sought for conquest, at least some unregulated province might be reduced to order. Among the families of Indian plants dealt with by Hooker and Thomson in their "Præcursores" one of the most fascinating, whether for the variety of its forms or the intricacy of their relationships, had been the Balsamineæ. Since 1859, when their paper appeared, a host of new Indian and Chinese forms had been reported; the characters met with in some of these appeared to invalidate earlier conclusions. To the study of this interesting group Hooker devoted his attention from 1904 onwards, evolving order out of an apparent chaos, and in the course of his studies placed those in charge of most of the important herbaria in Europe under a deep obligation, by supplying them with a uniform nomenclature for their specimens. On this work, which, so far at least as the Asiatic forms are concerned, had been practically completed, Hooker was engaged almost to the last.

Shortly summarised, and omitting here any reference to excursions into the domain of economic, morphological, and physiological botany, or to systematic studies of material from countries in which he did not himself travel, we find evidence of the existence of several definite lines of active interest, athwart which fell the shadow of various outstanding events in Hooker's career. The record indicates that Hooker's strongest and earliest predilections were perhaps towards the study of cryptogamic plants and work on fossil botany. The first predilection reached its culmination in 1844, when he returned from the circumpolar expedition on which he had started in 1839. The pressure exercised by problems, to the elucidation of which the evidence of flowering plants with their more special organisation and more restricted distribution is of greater value, gradually led to the abandonment of this field of study, which was not re-entered after he left for India in 1847. The predilection for work on fossil botany naturally reached its culmination while Hooker was attached to the Geological Survey. Its influence, though not entirely inhibited, was less active after Hooker's return from the East, and this field of study was abandoned when he became assistant director of Kew in 1855.

The predilection for the study of those problems that relate to the origination and distribution of species, to which his experience as a field naturalist on circumpolar islands and among the peaks and valleys of the Himalayas had given so great an impetus, reached its culmination while he was assistant director at Kew, and is manifested most strongly in the classical essays which date from 1860 to 1866. Without attempting to estimate the interaction effects of the work of Darwin on that of Hooker and *vice versa*, we may here direct attention to the fact of their existence. Nor could it be otherwise; the two men studied and wrote, on terms of intimate and affectionate friendship, in an atmosphere surcharged with great and pregnant thought.

With Hooker's succession to the directorship of Kew in 1865, the Antarctic work had practically ended, for the concluding moiety of the New Zealand handbook appeared in 1867. He was now able to do for India what he had already done for Tasmania and New Zealand, and if, when he retired in 1885, only half of his Indian systematic work had been accomplished, there was no break in its continuity. If we except his masterly sketch of the vegetation of India, prepared after the "Indian Flora" had been completed, we are without a record of his conclusions from Indian botanical evidence, comparable with the brilliant generalisations based on his study of the Arctic, Antarctic, and insular floras of the globe. This may be a cause for regret; it can be no cause for surprise. Not only is the Indian field the wider of the two; Hooker completed the essential preliminary spadework in the other during the sixteen years between 1844 and 1860, whereas the corresponding Indian toil exacted over forty years of labour between 1854 and 1897. When the Indian preliminary work was done it only served to prove that the relationships of the Indian, Malayan, and Chinese floras are so intimate as to demand their conjoint consideration.

The completion of the "Indian Flora" in 1897, rather than the demission of the directorship at Kew, marks the close of a period in Hooker's work. The next epoch, a comparatively brief one, was devoted to the performance of acts of piety to the memory and regard for the wishes of predecessors or of contemporaries whom he had outlived. These tasks ended, the evening of his life was devoted by Hooker to work which in many respects was, even for one so wide in his range and so varied in his interests, a new departure. His great "Antarctic Flora," his still greater Indian one, are splendid examples of broad canvases upon which in bold and striking lines the hand of a master has depicted the salient and essential features of a highly diversified landscape, and no one has ever portrayed with a surer touch. In the work to which Hooker devoted the closing years of his life, he has treated a single natural family as a precious gem, upon which, with a hand as sure as the one that has given us the ample atmosphere of his great pictures, he has engraved an exquisite intaglio.

To offer here an estimate of the quality of Hooker's work would surely be out of place. That task has already been performed in the pages of NATURE by one who was in the strictest sense Hooker's contemporary, and who, if he had not the advantage of such perspective as time affords, at least had all the benefit of distance in space to aid his judgment. It is sufficient here to say that the estimate made in 1877 has been fully sustained by all that has happened since; it is, moreover, interesting to reflect that the hope then so fondly expressed that Hooker, already in his sixtieth year, might still be only in mid-career has been fulfilled almost to a day. If it be urged that in one respect the judgment of 1877 is at a disadvantage as being from the pen of one who, like Darwin, was bound to Hooker by the ties of almost lifelong affection, then we can only say that no one now alive who has enjoyed the privilege of Hooker's acquaintance may venture to judge his work, because to know Hooker was to love him. The breadth of his interests, the depth of his knowledge, and the wisdom of his counsel combined to inspire reverence and regard. But above all these qualities, and beyond the singular charm of his manner, shone the unstudied and unstinted kindness which compelled affection.

A member of the Linnean Society since 1842, Hooker was a member of the council during twenty-four years, and for fifteen of these was one of its vice-presidents. He was also a member of the Geological Society, which he joined in 1846. He was elected a fellow of the Royal Society in 1847, and served on the council during seventeen years, for six of these as a vice-president and for five as president. A correspondent of the Institute and a member of the Academies of Berlin, Bologna, Boston, Brussels, Copenhagen, Florence, Göttingen, Munich, Rome, St. Petersburg,

Stockholm, and Vienna, he enjoyed, in addition, the freedom of practically every society or corporation devoted to the promotion of natural or technical knowledge within and beyond the British Empire. Not a few of these bodies have bestowed on Hooker still further distinctions. On the recommendation of the Royal Society he received a Royal medal in 1854; by the same society he was awarded the Copley medal, its highest honour, in 1887, and the Darwin medal in 1892. From the Society of Arts he received their Albert medal in 1883; from the Geographical Society their Founder's medal in 1884; from the Linnean Society their Linnean medal in 1888, a medal struck to celebrate his own eightieth birthday in 1897, and one of the medals struck in 1908 to commemorate the fiftieth anniversary of the publication of the joint communication of Darwin and Wallace on natural selection, in the original presentation of which to the society he had played so important a part. The Manchester Philosophical Society awarded him a medal in 1898, and in 1907 he received, in circumstances of singular dignity, from the Swedish Academy, what he himself has characterised as the crowning honour of his long life—the solitary medal, struck especially for the occasion, to commemorate the two hundredth anniversary of the birth of the great Linnæus.

Among his academic distinctions were the honorary degree of D.C.L., conferred upon him by the University of Oxford, and that of LL.D. from the Universities of Cambridge, Edinburgh, Dublin, and his own *alma mater*, Glasgow.

His foreign distinctions have included membership of the Royal Swedish Order of the Polar Star and the Royal Prussian Order "Pour le Mérite." By his own Government he was made a C.B. in 1869, the year following his presidentship of the British Association; he was made a K.C.S.I. in 1877, towards the close of his presidentship of the Royal Society. He was in 1897 promoted to the grade of G.C.S.I., when, in his eightieth year, the "Flora of British India" was completed; and in 1907, on his ninetieth birthday, he received the Order of Merit.

Hale and robust in his venerable old age, the veteran Hooker not only attended the Darwin-Wallace celebration organised by the Linnean Society in 1908, addressing the delegates and fellows present in a speech which recounted the part played by himself half a century earlier; he also attended the celebration at Cambridge in 1909 which commemorated the centenary of the birth of his friend Darwin. At work until within a few weeks of his death, and keenly interested in current topics to the last, Hooker passed peacefully away in his sleep, at his residence, The Camp, near Sunningdale, at midnight on Sunday, December 10. As was befitting, an invitation was offered to receive his remains in Westminster Abbey. Hooker had, however, expressed his wish that they should rest in the tomb in which his illustrious father's body was laid. This wish was fulfilled, and on Friday, December 15, he was buried in the family grave in the old churchyard of Kew. The *cortège* followed the coffin to the church, as was meet, from the house so long occupied by, and so full of memories connected with, his father and himself. At Kew, where so much of what he accomplished was done, he sleeps with his people, and Kew with its old churchyard is now more sacred even than it was to botanical pilgrims.

Among the mourners were the following members of the family, representatives of scientific societies and other institutions, and fellows of the Royal and the Linnean Societies:—

Lady Hooker (widow), Miss Grace Hooker (daughter), Mr. William Hooker, Dr. and Mrs. Charles Hooker, Mr. R. H. Hooker, Mr. R. S. Hooker, Sir W. T. Thiselton-Dyer, Miss Thiselton-Dyer, Mr. G. H. Thiselton-Dyer, Miss Symonds, Mr. R. Symonds, Mrs. Calverley-Bewicke, Mr. R. Woodward, Mr. R. Woodward, jun., Rev. G. Barker, Mr. G. Barker, Mrs. Crowder, Captain A. L. Henslow, Mr. Malleson, Mr. Murray, Miss Palgrave, Mrs. Paul Waterhouse, Miss M. Smith, Sir Arthur and Lady Rücker, the Hon. Mrs. H. Darwin, Mrs. Prain, Miss Younghusband, Mr. A. H. Lyell, Captain F. H. Lyell, Dr. Trail, Rev. A. G. Musgrave; the servants from The Camp, Sunningdale. Royal Society: Sir A. Geikie (president), Sir J. Larmor and Sir J. R. Bradford (secretaries), Lieut.-Colonel A. W. Alcock (council), and Prof. Bayley Balfour, Regius Keeper of the Botanic Garden, Edinburgh. Society of Antiquaries: Dr. C. H. Read (president). Linnean Society: Dr. D. H. Scott (president), Dr. B. D. Jackson and Dr. O. Stapf (secretaries). Geological Society: Prof. W. W. Watts (president), Prof. J. W. Judd (past-president). Royal Geographical Society: Mr. W. E. Darwin, Lieut.-Colonel H. H. Godwin-Austen. British Science Guild: Sir Norman and Lady Lockyer. Entomological Society: Prof. Meldola. British Medical Association: Mr. G. A. Peake. Royal Horticultural Society: Sir D. Morris, Mr. J. H. Veitch. Pharmaceutical Society: Mr. E. M. Holmes. University of Glasgow: Prof. F. O. Bower. Natural History Museum: Mr. E. G. Baker. West Indies: Mr. W. Fawcett. Royal Botanic Gardens, Kew: The Director, with the whole of the permanent staff, and with detachments representing the constabulary and the labour departments. Sir G. Darwin, Dr. F. Darwin, Sir A. Church, Prof. S. H. Vines, Mr. G. C. Druce, Prof. D. Oliver, Prof. F. W. Oliver, Mr. A. Henry, Dr. A. Günther, Prof. G. S. Boulger, Mr. J. S. Gamble, Mr. W. B. Hemsley, Mr. J. Britten, Mr. J. R. Drummond, and Dr. F. N. Williams.

NOTES.

We are pleased to be able to report that Dr. R. T. Glazebrook, the director of the National Physical Laboratory, who has for some time been seriously ill with enteric fever, has recently been making good progress towards recovery. A marked improvement has been shown during the last few days, and it is hoped that he may shortly be regarded as convalescent.

The Rt. Hon. the Earl of Cromer, G.C.B., and the Hon. Lionel Walter Rothschild, have been elected fellows of the Royal Society under the statute which empowers the council once in every two years to recommend to the society for election not more than two persons who in their opinion have rendered conspicuous service to the cause of science. The following have been elected foreign members of the Royal Society:—Dr. Johann Oscar Backlund, of Pulkowa, Imperial Astronomer of Russia; Dr. Heinrich Ritter von Groth, professor of mineralogy in the University of Munich; Heinrich Kayser, professor of physics in the University of Bonn; M. Joseph Achille Le Bel, of Paris, the distinguished chemist; and Klement A. Timiriazeff, professor of botany in the University of Moscow.

At a meeting of the executive committee of the British Science Guild, held on December 13, it was decided that the lecture scheme recently proposed should be commenced at the end of January. Sir Edward Brabrook agreed to read the first paper, on the scientific aspects of charitable effort. Prof. Perry will give a paper on problems in technical education in connection with national industries, and Mr. Frederick Verney on agricultural problems. After the reading of papers the meetings will be open for discussion. The meetings will be held in the rooms of the Chemical Society at dates to be announced later.

The conditions just issued by the War Office for the Military Aëroplane Competition have met with general

approval, and as they are frankly based on the recent French competition rules, and call in some instances for more difficult tests, it is felt that the winning machines will represent the best productions at present obtainable. The prizes are divided into two classes: (*a*) For aëroplanes made in any country (open to the world), first prize, 4000*l.*; second prize, 2000*l.* (*b*) For aëroplanes manufactured wholly in Great Britain, except the engines (open to British subjects), first prize, 1500*l.*; two second prizes, 1000*l.* each; three third prizes, 500*l.* each. There are, in addition, consolation awards of 100*l.* each for ten machines which undergo all tests and do not receive a prize, and the War Office is to have the option of buying any of the prize machines at 1000*l.* apiece. The chief conditions to be fulfilled are as follows:—The machine, which must be a two-seater fitted with dual controls, must rise without damage from long grass, clover, or harrowed land in 100 yards in a calm, carrying a live load of 350 lb. in addition to instruments and oil and fuel for 4½ hours' running. In rising, the height of 1000 feet must be reached in five minutes, and it must fly for three hours continuously, of which time one hour must be passed at an altitude of 4500 feet. Before landing, a glide of not more than 1000 feet will be required, and the angle must be not less than 1 in 6. The landing must be made without damage on any cultivated ground, including rough plough. Among the desirable attributes of the aëroplane are mentioned a silencer to the engine, flexibility of speed, and an engine capable of being started from on board.

IT is with much regret that we see the announcement of the sudden death of Prof. Andrew G. Ashcroft, of the City and Guilds (Engineering) College, South Kensington, S.W., at fifty-two years of age. Prof. Ashcroft was a student at University College, London, and at the conclusion of his student career he was attached to the staff of the Engineering School. For some time he was engaged in constructional engineering work at the Alexandra Palace, and in other practical work of a similar nature. He returned to the Engineering School of University College, London, to act as assistant to Prof. T. H. Beare and Prof. (now Sir) Alexander Kennedy. Whilst acting in this capacity he lectured on engineering subjects at the East London College, then the People's Palace. At this period of his career, coincident with the recognition of the importance of technical education, he was appointed head of the Woolwich Polytechnic, and his work in this position showed that he was a shrewd and capable organiser. He left Woolwich to take up the work of assistant professor of civil and mechanical engineering at the Central Technical College, London. Prof. Ashcroft was keenly interested in the subject of the strength of materials, and was an expert in the measurement of small strains. Amongst other instruments, he designed an extensometer for measuring elastic strains; a delicate cross-strain measurer for the determination of Poisson's ratio; and a hand-testing machine for small tension pieces with a specially delicate autographic recorder. His written contributions to various societies include papers on properties of malleable iron, instruments of precision, and the measurement of air supply to internal-combustion engines. Prof. Ashcroft was a member of many societies, and took an active interest in the welfare of each one of the numerous social clubs which exist at the college where he worked. He was universally popular with the students, and the engineering profession is the poorer for the loss of so attractive a personality.

A SERIOUS explosion, resulting in injury to eighteen officers and men, occurred on December 12 during certain trials which were being carried out on board H.M.S. *Orion* at Portsmouth. From the newspaper accounts it appears that official tests of one of the dynamos were in progress when the explosion took place. The explanations put forward attribute the accident to the ignition of inflammable vapour given off from the oil used as a lubricant of the dynamo. One suggestion is that the production of vapour was due to overheating of the bearings: this would imply either that the lubricant was unsuitable or that it was not properly applied. Whether in this particular case the explanation is the true one or not, it seems at least probable. Lubricating oils are generally composed of high-density petroleum products, used either alone or mixed with a proportion of vegetable or animal oil. Numerous varieties are made to suit different types of machinery. For each type, of course, it is important to choose the appropriate lubricant. As regards inflammability, it is well known that petrol and ordinary petroleum oil for burning give off vapour at relatively low temperatures, but it is probably not so well recognised that at higher temperatures some lubricating oils may do the same. In fact, a determination of the flashing point, or at least a proof that the oil does not "flash" below a given temperature, is usually required in deciding upon the suitability of certain kinds of mineral oil for use as lubricants.

THE annual Christmas course of juvenile lectures at the Royal Institution will begin on Thursday next, December 28, at three o'clock, when Dr. P. Chalmers Mitchell will deliver the first of six lectures on "The Childhood of Animals."

AT the recent annual meeting of the Yorkshire Numismatic Fellowship, held at Leeds, Mr. T. Sheppard, of the Municipal Museum, Hull, was elected the president for the year 1912, and editor of the society's Proceedings.

A JOINT meeting of the Institution of Mining and Metallurgy and the Canadian Mining Institute will be held at Toronto on March 6, 1912, and the following days. The meetings for the reading and discussion of papers will occupy three days, March 6, 7, and 8. The annual dinner of the Canadian Institute will be held on March 8, and on March 9 an excursion to the mining districts of Cobalt and Porcupine will be arranged, provided a sufficient number of the members of the English institution wish to visit those localities. Further details of the arrangements may be obtained from the secretary of the institution, Mr. C. McDermid, at Salisbury House, London, E.C.

IN proposing the toast of "The Institution of Mining and Metallurgy" at the annual dinner of the institution, held on December 15 at the Savoy Hotel, Sir Alfred Keogh announced that the Bessemer Memorial Committee will, in January, hand over to the Royal School of Mines the laboratory which it has presented to the Imperial College of Science and Technology. Mr. Sulman, in responding to the toast, said that the world's production of gold in the form of standard metal since 1880 has exceeded 1,000,000,000*l.* sterling, more than one-half of which has been won from mines within the British Dominions. The British capital involved in metalliferous mining, apart from coal and iron, during the past twenty-five years exceeds 900,000,000*l.* sterling. During the past four years there has been subscribed as working capital for metalliferous mining, outside coal and iron, above 4,500,000*l.* sterling.

IT is well known that the late Mr. J. R. Mortimer, the Driffield antiquary, was an authority on the prehistoric and other earthworks of East Yorkshire, and during the past half-century he made a careful survey of all that

remains relating to the military and domestic life of the early people who built them, a subject upon which he wrote many papers. Several of the structures which were known to Mr. Mortimer forty or fifty years ago, or less, have since entirely disappeared, as a result of agricultural and other operations. Fortunately, Mr. Mortimer carefully recorded his observations upon a large series of Ordnance maps of the district, and also particulars of the barrows, the Roman remains, the pits from which he obtained his geological specimens (most of which are now closed), &c. This valuable collection of maps has been presented by Major Mortimer to the Municipal Museum at Hull, where it can be referred to by students and others interested. In addition are large numbers of sketches, plans, photographs, negatives, &c., bearing upon East Yorkshire antiquities.

THE second annual general meeting of the Society of Engineers (Incorporated) was held on December 11, Mr. John Kennedy, vice-president, being in the chair. The following were elected as the council and officers for 1912:—*President*, J. Kennedy; *vice-presidents*, A. Valon, H. C. H. Shenton, N. Scorgie; *members of council*, H. Adams, C. T. Walrond, P. Griffith, T. E. Bower, H. C. Adams, J. R. Bell, S. Cowper-Coles, H. P. Maybury, B. H. M. Hewett, F. H. Hummel; *associate member of council*, E. Scott-Snell; *hon. secretary and treasurer*, D. B. Butler. It was announced that premiums for papers read at meetings and published in the Journal during 1911 had been awarded as follows:—the president's gold medal to Mr. W. R. Baldwin-Wiseman, for his paper on the administrative aspect of water conservancy; the Bessemer premium of books or instruments, to the value of 5*l*. 5*s*., to Mr. R. W. A. Brewer, for his paper on two-stroke cycle engines; the Clarke premium, value 5*l*. 5*s*., to Mr. T. J. Gueritte, for his paper on the mechanical installation and upkeep of permanent way on railways; a society's premium, value 3*l*. 3*s*., to Mr. E. Kilburn Scott, for his paper on nitrogen products made with the aid of electric power; a society's premium, value 3*l*. 3*s*., to Mr. Frank G. Woollard, for his paper entitled "Some Notes on Drawing-office Organisation."

THE annual general meeting of the Scottish Meteorological Society was held on December 12. From the report of the council, which was adopted at the meeting, we learn that during the past twelve months several additions have been made to the society's system of stations. A fully equipped station has been established by Mr. G. Craig Sellar at Ardtornish, on the Sound of Mull, and represents effectively an interesting region from which observations were greatly needed. New stations have also been established at Aviemore by the Aviemore Station Hotel Company, and at Carrbridge by the Rev. Andrew Doak, and these will add to the scanty knowledge of the meteorology of the Central Highlands. The council points out once more that there is urgent need for additional information regarding the rainfall of the Highland area and the north of Scotland. Apart from the purely scientific value of rainfall records, the rainfall of a district touches practical and sporting interests at many points, and it seems to the council that it may reasonably look to large landowners and shooting tenants for help. It may be pointed out that the final report of the recent committee of inquiry on grouse disease has something to say on the importance of meteorological conditions in relation to the distribution and the health of grouse. It appears that where rainfall is very heavy there is little disease, but grouse are few, the scarcity of the birds being due probably to the deleterious effect on heather of a high rainfall. The council elected for the ensuing twelve months is as follows:—*President*, Prof. A. Crum Brown, F.R.S.; *vice-presidents*, Ralph Richardson, W.S., Dr. C. G. Knott; *council*, Sir David Paulin, Gilbert Thomson, H. M. Cadell, Sir A. Buchan-Hepburn, Bart., G. G. Chisholm, M. M'Callum Fairgrieve, J. Mackay Bernard, Dr. J. R. Milne, T. S. Muir; *hon. secretaries*, R. T. Omond, E. M. Wedderburn, W.S.; *hon. treasurer*, W. B. Wilson, W.S.

IN a report presented to the French Institute of Anthropology, published in *Comptes rendus* for March-June, M. Boule discusses the morphology of the mammoth as displayed in recent discoveries of Palæolithic art. He points out that certain physical peculiarities of the animal, which were only recently established by the discovery of a specimen by M. Wollosowitch at Sanga-Iurach in 1908, already appear in stone carvings dating from the Palæolithic age.

IN vol. xxii., Nos. 4–5, of *L'Anthropologie*, Dr. Lalanne and L'Abbé H. Breuil describe a series of remarkable Palæolithic sculptures on a cliff at Cap-Blanc, Laussel, Dordogne. Among the animals represented are a bison and a pair of horses, depicted in the usual vigorous style of the art of that period. This discovery supplies a welcome addition to the cave sculptures of a similar class already familiar to archæologists. It is now proved that these early artists, in addition to work carried out by torchlight in dark, damp caves, executed similar sculptures in the open air.

THE work of the modern school of French anthropology is largely devoted to the preparation of elaborate memoirs in which the results of the investigation of specially interesting races are summed up and criticised, with a complete apparatus of facts and statistics. Such is the admirable account contributed to vol. xxii., Nos. 4–5, of *L'Anthropologie* by Dr. Poutrin, entitled "Les Négrilles du Centre Africain (type sous-dolichocéphale)," in which he has collected all the information at present available on the Pygmy races. The introduction, illustrated by a map, shows the distribution of these people, and is followed by a historical account of exploration and an elaborate survey of the physical characteristics. Probably no account of this remarkable race, already available to students, contains a more complete survey of the ethnological problems connected with the Pygmies of Africa.

ACCORDING to the fourth annual report (1910–11) of the National Museum of Wales, the designs for the new building have been considerably modified, with, it is believed, a great improvement in the general appearance of the structure. Illustrations are given of the exterior and of the entrance hall, together with plans of the ground-floor and the two floors above. A contract has been signed for the construction of the basement and sub-basement for that portion of the building proposed to be erected in the first instance, which includes the south block and the lecture theatre and gallery above, and work on this was commenced in September last. Considerable progress has been made in collecting specimens for exhibition and study.

WE have received a copy of a petition from the natives of India presented to H.M. the King at the Delhi Durbar (together with a covering appeal signed by K. S. Jassawalla, of 45 Courthope Road, Hampstead), praying that the supply of beef required for the British Army in India may in future be obtained from Australia in place of India itself. The petition is accompanied by a large illustration showing the various uses to which Indian cattle are put. So great is the demand in the country for cattle for purposes of draught and agriculture that, according to the petition, cows are chiefly slaughtered for beef. This practice is one of the causes which have led to a great diminu-

tion in the number of cattle in the country, with a corresponding rise in the price of milk and ghi (native butter). It is further urged that the quality of Indian beef is far inferior to that of Australian beef, and likewise that the use of the latter in the Army commissariat would not entail any very great additional cost.

MR. A. H. THAYER's suggestive observations upon protective coloration in nature have been described in these columns on more than one occasion, and his son's beautifully illustrated work upon it was reviewed in detail a little more than a year ago (October 27, 1910). A number of illustrations from that work are reproduced in colour in the December number of *Pearson's Magazine*, and the principle they exemplify is described in an instructive article by Mr. Marcus Woodward. Mr. Thayer's view is that it is the rule for animals to be coloured like the background which most concerns their feeding and escape from attack. There are limitations to the application of this interpretation of obliterative colouring throughout the animal kingdom; but there is no question as to the great importance of the principle of countershading in nature, and the article and pictures in *Pearson's Magazine* should be the means of interesting many people in it.

THE latest issue of *The Kew Bulletin* (No. 9) is mainly occupied by systematic articles. The most interesting is a description of six new species of Impatiens from Travancore and Cochin, contributed by the late Sir Joseph Hooker. The list of additions to the wild fauna and flora of the gardens is due in great measure to the collection of specimens by members of the garden staff. Noteworthy is the announcement of a heath from Cornwall which appears to be a natural hybrid between *Erica tetralix* and *E. vagans*.

THE annual Kew list of seeds of hardy herbaceous plants and of trees and shrubs available for exchange with botanic gardens and regular correspondents has been published as Appendix I. to *The Kew Bulletin* (1912). The list reflects in some measure the outcome of the remarkably fine summer, notably in the ripening of the seeds of trees and shrubs; thus there are offered for exchange the seeds of *Clerodendron dichotomum*, which has fruited at Kew for the first time on record, *Koelreuteria paniculata*, *Buddleia globosa*, and two species of Halesia.

BOTANICAL exploration in India is summarised by Major Gage, as director of the botanical survey, in his report for the year 1910–11. An expedition to the south-east corner of Sikkim was undertaken by Mr. W. W. Smith. Captain R. W. Macgregor presented an interesting collection of specimens from the Southern Shan States, and a smaller collection was forwarded by Mr. Burns from Bombay. In the south, the most important contribution was made by Mr. A. Meebold, as the result of an extensive tour through the States of Cochin and Travancore. A second fasciculus of the catalogue of non-herbaceous phanerogams cultivated in the Calcutta Botanical Gardens has been published as vol. v., No. 2, of the Records of the Botanical Survey of India.

ON Monday, December 18, Dr. D. T. Macdougal, director of the department of botanical research of the Carnegie Institution of Washington, lectured before the Royal Geographical Society on the North American deserts. After describing the general characters of desert areas, and explaining the importance of the various factors involved, he passed on to give a short account of the study of such regions which is being carried on by the Carnegie Institution. A large series of lantern-slides, many of them in colour, showed very instructively the character of the desert regions of Arizona and California, and of the types of vegetation which are able to flourish there both under normal conditions and also by the aid of artificial constructions, such as the concrete walls which are sunk in the detritus-filling valley floors in order to hold up to a higher level the water, which otherwise flows at a depth which is out of the reach of surface vegetation. The formation of the Salton Lake was also described, and its effect on the vegetation of the basin was illustrated. Dr. Macdougal is leaving shortly to visit the deserts of Egypt and the northern Sudan.

IN the Monthly Meteorological Chart of the Indian Ocean for December, issued by authority of the Meteorological Committee, a considerable space (as in previous months) is devoted to a useful discussion of ice reports, relating to the southern hemisphere, which subject has for many years occupied the serious attention of the office. In the Southern Ocean icebergs are most frequently met with to the north-east of Cape Horn, south-east of the Cape of Good Hope, midway between Kerguelen and the meridian of Cape Leeuwin, and midway between New Zealand and Cape Horn. Tables of the monthly and annual frequency of the bergs from 1885 to 1910 show that the periods of maxima and minima vary irregularly; the years of greatest frequency were 1893 and 1906. In the chart for the North Atlantic the ice conditions are also discussed. A sub-chart of the exceptional drifts and heights of bergs shows that the latter were most frequent in the ten-degree square of lat. 40°–50° N. and long. 40°–50° W., but some few were observed nearly so far south as lat. 30° N. The first ice seen in 1911 was on January 28, near lat. 47° N. and long. 52° W.

IN an interesting paper recently published in the *Bollettino* of the Italian Seismological Society (vol. xv., 1911, pp. 144–53), Prof. G. Grablovitz has traced the variations in the mean level of the sea at Ischia during more than twenty years. From 1890 to 1894 the mean level furnished by the mareograph records remained not far from constant, but from 1895 onwards there has been a marked change, after the effects of barometric variation have been allowed for. The change is not always in one direction; but during the sixteen years from 1895 to 1910 there has been, on the whole, a rise in the sea-level, the average annual amount being 3 or 4 millimetres a year. The mareograph records at Genoa also indicate a gradual, though much less pronounced, rise in the apparent level of the sea.

IN his well-known investigations on the after-shocks of earthquakes Prof. Omori finds that the law of decline in frequency is of the form $y=k/(x+h)$, where y is the daily number of after-shocks at time x after the parent earthquake, and h and k are constants which vary with every earthquake. Mr. A. Cavasino has recently examined the validity of this formula in regard to the after-shocks of the Riviera earthquake of 1887, one of the first earthquakes in which the after-shocks were studied in detail (*Boll. della Soc. Sismol. Ital.*, vol. xv., 1911, pp. 129–43). Determining the values of the constants from the recorded numbers of sensible shocks during the first five days, he shows that the agreement between the numbers furnished by the formula and of those actually observed is at first fairly close, but that, after the lapse of a few years, the formula fails to give correct results. The discrepancy may be due partly, as he suggests, to the difficulty of determining the average seismicity of the district. It may also be due to the small number of records used in determining the constants of the equation.

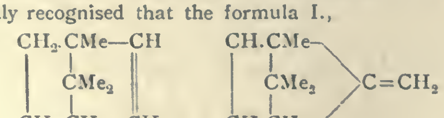
IN the *Atti dei Lincei*, xx. (2), 6, Prof. A. Garbasso describes a repetition, with modern apparatus, of the classical experiment of Volta and Bennet, according to which the flame of a candle discharges the conductor of an electroscope. In this case a Ramsden's electric machine and an Exner electroscope were used at a distance of 15 metres apart, and it was observed that on working the machine the electroscope readings increased; on stopping it they decreased, then rose to a maximum, and then again fell.

SIR GEORGE GREENHILL, writing in *The American Journal for Mathematics*, xxxiii., 4, develops the result obtained by G. W. Hill, according to which the potential of a homogeneous spherical segment (*e.g.* a flat lens) at any point can be made to depend on elliptic integrals. This result depends on the method of dissection employed; in this case the segment must be supposed cut into slices perpendicular to the line joining the centre to the point at which the potential is required.

ACCORDING to a paper by Messrs. Kinoshita and Ichinohe in vol. iii. of the Memoirs of the Science and Engineering College of the University of Kyoto, the ionisation current from a metal filament when heated above 2400° absolute ceases to be represented by Prof. Richardson's equation $C=A\sqrt{\theta}.e^{-b/\theta}$, where C is the value of the saturation current, θ the absolute temperature, and A and b constants depending on the nature of the metal. They put this down to the fact that the equation is deduced on the assumption that the whole of the saturation current is carried by the ions emitted by the heated filament. At the high temperatures they attained they consider the kinetic energy of the moving electrons sufficient to enable them to ionise the gas molecules with which they come into contact. The magnitude of the current thus produced appears to be roughly half that of the total current observed.

THE *Verhandlungen der Deutschen Physikalischen Gesellschaft* for November 15 contains a short report laid before the meeting of the Naturforscher und Aerzte at Karlsruhe by Drs. Scheel and Heuse, on the measurements of the specific heat of air at ordinary and at very low temperatures recently made at the Reichsanstalt. The method used was that of "continuous flow," the air passing through a vacuum-protected tube in which it was heated by a wire carrying an electric current, its temperature on entering and in leaving being measured by platinum thermometers. The results for the specific heat are as follows:—at 20° C., 0·241; at −78° C., 0·243; at −183° C., 0·252. There is, therefore, a distinct increase of the specific heat as the temperature decreases. The result at 20° C. agrees to within 1 part in 1000 with that obtained by the same method by Dr. Swann, and published in the Proceedings of the Royal Society of London in 1909. The complete account of the work of Drs. Scheel and Heuse is to appear in the *Annalen der Physik*.

THE November issue of the Chemical Society's Journal contains a paper by Prof. G. G. Henderson and Mr. I. M. Heilbron on the constitution of camphene. It is now generally recognised that the formula I.,



I. Bornylene. II. Camphene.

originally proposed by Bredt, is in reality that of the closely related bornylene, as is shown by its preparation from borneol through the xanthate, and by the ease with which it is converted into camphoric acid by oxidation. A great many of the reactions of camphene indicate the presence of the methylene group $>C=CH_2$ in this compound, and on the basis of much experimental evidence the authors consider the formula II., originally proposed by Semmler, to be the best expression of the known facts.

AN interesting case of isomerism is discussed by Messrs. Laws and Sidgwick in the November number of the Chemical Society's Journal. The phenylhydrazone of acetaldehyde possesses the remarkable property that the α-form, melting at 98°, and the β-form, melting at 56°, can be converted almost quantitatively one into the other by the action of a mere trace of acid or alkali; thus crystallisation from aqueous alcohol containing a trace of potassium hydroxide gave the high-melting α-form, whilst recrystallisation from aqueous alcohol containing a trace of sulphur dioxide gave the low-melting β-form. This peculiarity of the isomerism is obviously connected with a very small difference in the energy-content (and therefore in the stability) of the two forms. This factor is usually overbalanced by a marked difference in the solubility of the two forms, a difference which sometimes favours either the one or the other form according to the solvent from which the material is crystallised. But in the case under consideration the difference of solubility almost disappears on account of the fact that the two forms are isomorphous. Their interconversion can therefore take place with peculiar facility, and in the case of the solids may be brought about by gaseous acids and alkalis without producing any alteration in the appearance of the crystals.

Engineering for December 15 contains an account of some valuable experiments on the strength of thick hollow cylinders under internal pressure, carried out by Messrs. Gilbert Cook and Andrew Robertson at the University of Manchester. The object of the experiments was to test the various theories for the manner of failure, and cylinders both of cast iron and of mild steel were tested. In the case of cast iron, elastic limit and rupture are practically coincident; the results of the experiments show that the failure is determined solely by the maximum principal stress, and Lamé's formula,

$$p=f\frac{k^2-1}{k^2+1},$$

may be used directly. In this formula f is the stress at failure in simple tension, and k is the initial ratio of the diameters. In the mild-steel cylinders tested, initial yield took place when the pressure was about 20 per cent. in excess of that required by the shear-stress theory (Guest's law); the pressure may be calculated very nearly by the equation

$$p=0{\cdot}6f\frac{k^2-1}{k^2}.$$

Tests were also made on the ultimate strength of mild-steel cylinders. The results may be denoted empirically by the same formula that applies to cast iron.

WE have received from Messrs. James Woolley, Sons and Co., Ltd., of Victoria Bridge, Manchester, a copy of their "Scientists' Reference Book and Diary for 1912." In addition to a conveniently arranged diary, in which each week of the year is given a page, a reference book containing useful information as to important facts and constants continually required by workers in science is provided. The tables and other data have been carefully revised, and will prove of great service. The price of the publication is 1*s*. 6*d*.

THE report of the Clifton College Scientific Society for the year 1910–11 has been received. This year, for the first time, the report is illustrated. The numerous sections of the society were very active during the period under review, but the attendance at general meetings does not appear to have been so good as in previous sessions. The report shows that many of the masters join with the boys in their practical study, in leisure hours, of various branches of science. Great prominence is given to outdoor work of a kind likely to engender a love for scientific observation and research among the boys.

THE issue of "Hazell's Annual" for 1912 maintains the high character for usefulness which previous editions of this work of reference have gained. The contents have been revised to November 25 last, and the editor, Mr. Hammond Hall, claims that the compilation gives "the most recent and authoritative information on the topics of the day." One section of the volume, running to forty-two pages, is entitled "The March of Science," and deals, among other subjects, with scientific progress in 1911, imperial research, and aërial navigation. This is the twenty-seventh year of issue of the annual. The price of the volume is 3*s*. 6*d*. net.

COPIES of the 1912 issues of the well-known works of reference published annually by Messrs. A. and C. Black have been received. "Who's Who" is larger than ever; the 1911 edition ran to 2246 pages, but the new volume contains 2364 pages. There is a remarkable variation in the lengths of the autobiographies contained in this indispensable volume; some consist of two or three lines only, while others take up nearly a page. It is satisfactory to find, in view of the important part which science takes in modern States, that due prominence is given to men of science in this record of living notabilities. "Who's Who Year-book" contains, as usual, the well-arranged tables which were formerly a popular feature in "Who's Who" itself. "The Englishwoman's Year-book and Directory" should be in the hands of every woman who is engaged in public work; it is crammed with useful information of a trustworthy kind. "The Writers' and Artists' Year-book" is, its editor says, chiefly for the use of those persons who wish to make money by their pen or brush.

OUR ASTRONOMICAL COLUMN.

MARS.—In a telegram, dated November 29, from Sétif, to the *Astronomische Nachrichten*, M. Jarry-Desloges states that Mare Sirenum is persistently seen cut into three parts, and that Elison is easily perceptible. Later, on December 4, he reports that Juventæ Fons is now an easy object, L. Phœnicis is triple, Bathys is apparently effaced, the Aonius Sinus encroaches on Thaumasia, and the south polar spot, in 95°, is 0·7″ in diameter.

The December number of *L'Astronomie* contains several drawings of the planet by M. Quénisset and others, with descriptions of the different features observed during October and November. The outstanding feature on October 17 was Tartarus, which, leaving the M. Sirenum at its eastern point, traversed nearly the complete disc and joined up with Trivium Charontis.

On photographs taken on one plate by Prof. Lowell on October 11, M. Flammarion has recognised fifteen different Martian features in the L. Solis region, including several canals.

BORRELLY'S COMET, 1911*e*.—Dr. Ristenpart communicates the position of comet 1911*e*, as observed at Santiago on November 26, to No. 4541 of the *Astronomische Nachrichten*, and adds that the comet was round, was less than 1′ in diameter, had a nucleus and a tail, the latter less than 30′ long, and that its magnitude was 9·0; the corrections to the ephemeris at 10h. 57·6m. (Santiago M.T.) on November 26 were +0·3′ and +0·2′.

SPIRAL STRUCTURE IN NEBULÆ.—In an interesting article published in No. 3, vol. xxxiv., of the *Astrophysical Journal*, Mr. William Sutherland discusses the relation between the distribution of the planets and the probability of their origin in a spiral nebula. He shows that the equation expressing Bode's law may be developed to show that the planetary distances are derived from two equi-angular spirals, thus leading to the idea that the solar system in its evolution passed through the spiral form so common among nebulæ, the spiral being of a simple logarithmic form. He pictures the elementary nebula as made up of meteorites rotating about a centre, the meteorites being uniformly distributed. Collisions occur, reducing the rotational velocity of the colliding bodies, and the latter fall towards the centre; but they will fall spirally, owing to the common rotation of the mass, and thus spirals of condensation would be formed. Mr. Sutherland shows how these might finally agglomerate into two-armed spirals, in which local condensations might account for the considerable variation of mass among the planets; according to this scheme, the moon and other satellites were formed from subsidiary branches to the spiral arms. Comparisons between the calculated spirality of several nebulæ and that calculated for the solar nebula from the law of distribution of the planets shows the values to be of the same order, and thus lends support to Mr. Sutherland's theory.

PERMANENT DESIGNATIONS FOR RECENTLY DISCOVERED VARIABLE STARS.—In No. 4540 of the *Astronomische Nachrichten* the commission for the A.G. catalogue for variable stars publishes the permanent names allotted to variable stars discovered recently. From the notes it is seen that most of the discoveries were photographic, and that many of them were made at Harvard. A glance at the tabulated maxima and minima suggests that the field of discovery for variable-star observers is not yet closed, for we find ranges of three or four magnitudes, *e.g.* 9·5 to 12·8, among the fainter objects.

LUMINOSITIES AND RADII OF VARIOUS STARS.—Answering a question as to the relative sizes of the stars, Mr. J. B. Cannon, of the Dominion Observatory, gives some interesting figures in No. 5, vol. v., of the Journal of the Royal Astronomical Society of Canada; he also outlines the method whereby the figures were derived.

As the surface intensities of the various spectral types, taking that of the sun as unity, he adopts 12 for types A and B, 3 for type F, 1 for type G, and 0·5 for types K and M, and derives the luminosities and radii of eighteen well-known stars. Rigel, with a radius 41·5, has a luminosity 20,614 times that of the sun. Only two stars, α Aquilæ and β Leonis, are calculated to be the same size as the sun, and are just over twelve times as luminous. The radius of the Pole Star is 5·9, and its luminosity 102, while Regulus, with six times the radius of the sun, is 423 times as luminous.

THE PHYSICAL SOCIETY'S EXHIBITION.

THE seventh annual exhibition of physical apparatus under the auspices of the Physical Society of London was held on Tuesday afternoon and evening, December 19, at the Imperial College of Science and Technology. The very large attendances at both sessions was evidence that the exhibition continues to serve a very useful purpose in bringing a knowledge of new apparatus to teachers and others interested in scientific work.

A discourse was given by the Hon. R. J. Strutt, F.R.S., at each session on electric discharge and the luminosity that survives it, in which the lecturer displayed some interesting and very pretty experiments on the afterglow which succeeds the passage of an electric discharge through nitrogen. A current of pure nitrogen was maintained through the discharge tube and passed into a large globe, in which it still maintained a yellow glow. The interaction of nitrogen in this state with nitric oxide and stannic chloride vapours was shown by the change in the colour of the glow to green and blue respectively when the vapours

were mingled with the nitrogen in the globe. Further experiments on the effect of pressure were made, and the causes of the phenomena briefly discussed.

Thirty-three firms exhibited their latest forms of physical apparatus. Only a few of the various new forms of instruments can be mentioned. A new galvanometer of the moving-magnet type was shown by the Cambridge Scientific Instrument Co., who claim for it a sensitiveness forty times that of their Broca type. The magnet system consists of two groups of very small magnets arranged on a fine glass stem, which is suspended from a quartz fibre. The coils are arranged in pairs similar to a Thomson galvanometer, and are designed to secure the maximum effect for a given resistance of copper by winding with different sizes of wire, beginning with the smallest size, and winding each layer so that it lies within the surface of which the polar equation is $r^2=d^2 \sin\theta$, where r is the length of radius, making an angle θ with the axis of the coil. The company displayed several other exhibits of their instruments for advanced work, including a Duddell oscillograph outfit for a 50,000-volt circuit. A new design of extensometer was shown by W. G. Pye and Co., for use in conjunction with a testing machine on bars and thick specimens. It was composed of the Ewing extensometer with the microscope replaced by an optical lever, and was designed to measure extensions of 1/100,000 of an inch. Several new designs of students' apparatus and a Kohlrausch bridge of new form were included among their other exhibits. A new vibragraph was shown by Siemens Brothers and Co., Ltd., consisting of a mercury reservoir with a floating mirror, by means of which a beam of light from a small glow-lamp is reflected on to a ground glass screen or photographic plate. The mercury ripples set up by the vibration of the body on which the reservoir is placed give an angular movement to the mirror, which thus produces on the plate or screen a clearly defined diagram of the vibration. The same company also showed a demonstration wireless-telegraphy set on the singing-spark system, and a number of frequency indicators.

New projection apparatus and a new level for very accurate surveying was shown by Carl Zeiss, Ltd. Photomicrographic apparatus, and an ultra-condenser for rendering an ordinary microscope suitable for ultra-microscopic observations were among the exhibits of Messrs. E. Leitz. Their latest pattern of high-vacuum oil pump was shown by A. C. Cossor, Ltd. The piston of the high-vacuum cylinder is actuated from outside by an electro-magnet, which is caused to move up and down, thus avoiding the use of a piston rod and possible leak at the stuffing boxes. The Foster Instrument Co. exhibited a simple strain-meter for observation of strains in any part of a structure, such as a girder of a bridge or frame of a ship.

Various types of switchboard instruments were shown by Nalder Bros., R. W. Paul, and the Weston Instrument Co. Among the exhibits of the last-named was a new line of alternating-current dynamometers, including wattmeters, frequency meters, and synchroscopes. R. W. Paul also exhibited a new and inexpensive form of potentiometer, various inductionless resistances, and a number of thermocouple pyrometers and temperature indicators. Messrs. Gambrell Bros. exhibited a new potentiometer for thermoelectric work, and instruments of various kinds for students' use. The Silica Syndicate displayed some wonderful examples of their wares. Electric furnaces were shown by J. J. Griffin and Sons, Ltd., together with quartz glass mercury thermometers for temperatures up to 750° C.

Demonstrations of Dr. Leonard Hill's colour vision apparatus were made at the stand of Messrs. Newton and Co. The degree of sensitivity of the eye for colours is ascertained by means of two identical spectra projected by an optical lantern from one and the same prism, and provided with separate adjustable screens for matching. Electrical apparatus for medical purposes was shown by the Sanitas Electrical Co., and X-ray apparatus by H. W. Cox and Co. E. Raymond-Barker's two-tone transmitter, exhibited by the India-Rubber, Gutta-Percha and Telegraph Works Co., Ltd., and F. Harrison Glew's radio-active preparations, are two of many other interesting exhibits, of which our space does not permit us to give more detailed account.

THE ASTRONOMICAL AND ASTROPHYSICAL SOCIETY OF AMERICA.[1]

FOR the first time in its history the Astronomical and Astrophysical Society of America this year held its annual meeting outside the United States, and it speaks well for the progress of the comparatively young Dominion Observatory that the *locale* was Ottawa. This feeling was made the subject of a special resolution, in which a very favourable opinion as to the character of the work done in every department was united with a recommendation that a more powerful telescope may soon be provided for use in the important radial-velocity work now being executed at this observatory.

Prof. E. C. Pickering was elected president, Profs. Frost and Campbell vice-presidents, and Mr. Plaskett, of the Dominion Observatory, was elected a councillor. A great number of papers were read during the five sessions held on August 23, 24, and 25, and the general feeling was that in every respect this twelfth annual meeting was eminently successful. We briefly note a few of the papers here.

Prof. Pickering read a paper in connection with the symposium on photographic astrometry, showing how the first point of Aries might be determined photographically.

Miss Cannon announced that the spectra of 762 double stars of magnitude 7·5 and brighter had been especially examined on the Harvard photographs, and also explained that an examination of some 131 stellar spectrograms taken with slit spectrographs was being made, in order to see whether the same system of classification can be applied to such spectra as was applied to the store of objective-prism spectra at Harvard. It is difficult to see why the classification should differ, although more details may be seen and so give finer divisions; but we hope that this work will not lead to further complications in the already complicated nomenclature of the Harvard system.

Mr. Parkhurst examined a number of stars given in a list by Prof. Pickering purporting to comprise "Fourth Type Stars not Red" (class R), and extended to include some ordinary red stars (class N). By his photo-visual magnitude method he finds that with one exception the stars are all redder than Aldebaran, and therefore no sharp line should be drawn between classes R and N.

Mr. Harper, of the Dominion Observatory, read a paper on the orbits of the spectroscopic components of d Bootis, and Mr. Joel Stebbins explained how the selenium photometer had revealed a range of 0·2 mag. in the brightness of Betelgeuse during 1910–11, and had shown δ Orionis (range 0·10 mag.) and β Aurigæ (range $<$0·10 mag.) to be eclipsing variables. Polaris too, as shown by Mr. E. S. King's examination of Harvard plates, has a variability of 0·108 mag.

Some results of a study of visual binary stars by Dr. H. N. Russell suggest that the whiter stars are very much brighter, for equal masses, than the redder stars, and that the stars of a given type are of equal mass and of equal luminosity. Examining some 349 stars of various spectral types, he finds that about half of them are very much brighter in proportion to their mass than the others. This half includes all the stars of the B type, among those examined, and some of every other type, and these stars may probably be classed as the "giant" stars of Hertzsprung's division, a class in which the systems are more or less uniformly of about ten times the sun's mass; no such uniformity is found in the average masses of the "dwarf" stars, which appear, in the average, to become less massive as they become redder. A pair of "giant" stars would emit some 150 to 250 times the light emitted by the sun—the higher value being for class B stars—whereas a pair of "dwarfs" if of the A class might give 30 times, and if of the K_5, or M, class, one-hundredth, the light emitted by the sun.

The 6-inch transit circle of the U.S. Naval Observatory has attacked its programme of fundamental stars, both the old ones and those for the International Chart, and its behaviour was described by Prof. Littell.

Dr. Humphrey's papers showed (1) that the various zones of the earth are not equally efficient radiators; both the

[1] Condensed from the secretary's report in *Science*, N.S., vol. xxxiv., No. 877, pp. 520–536.

equatorial and the polar zones are inefficient as compared with the middle latitude: this result is produced by the unequal distribution of cirrus clouds, which are the effective factors in determining the outgoing radiation; (2) where d is the depth of the water layer in millimetres, and e the partial pressure of the water vapour in millimetres of mercury, the thickness that would accrue if all the water vapour above any given level in the atmosphere, on cloudless days, were condensed, is expressed approximately by $d=2e$; this is some 13 per cent. less than the value, Hann's, heretofore commonly employed in bolometric work.

The reality of astronomical teaching in America was well illustrated by a thoughtful paper by Prof. Sarah F. Whiting, in which she urged the importance of daytime laboratory work in astronomy.

Prof. Very explained an attempt to form a standardised scale of intensities for the lines in the solar spectrum, and Miss Leavitt contributed a paper on the variable stars in the Small Magellanic Cloud; the stars are too faint for our present spectroscopic equipments, but the spectroscopic investigation of brighter stars having similar light-curves—*e.g.* UY Cygni—might prove very profitable. Prof. S. A. Mitchell described the radial velocities of 96 Herculis, which has four components, all measurable on some plates; the velocities range from -98 to $+74$ km. per sec. and the period is 50·2 days.

Prof. Tucker's description of the San Luis Observatory of the Carnegie Institution produces a feeling somewhat akin to envy for the facilities afforded by such an institution. The expedition left New York in August, 1908, and six months later the observatory and a dwelling for the ten observers were completed. Observations with the Pistor and Martins meridian circle of the Dudley Observatory were commenced in April, 1909, and 87,000 observations were completed when the work was brought to a close in January this year; the reductions will be completed at the Dudley Observatory.

The preliminary work done at the Dominion Observatory, sharing in the international cooperative scheme, on the rotation of the sun was explained by Mr. Plaskett. The mean of twenty-three plates taken during June and July this year gives an equatorial velocity of $2{\cdot}034 \pm 0{\cdot}004$ km., the probable error of a single plate being $\pm 0{\cdot}017$ km.; all the elements represented between λ 5500 and λ 5700 appear to share in a common velocity.

Halley's comet was the subject of papers by Prof. Barnard and Prof. Frost, respectively, the former giving the preliminary results determined from Mr. Ellerman's photographs taken at Hawaii, the second finding $+55$ km. per sec. as the radial velocity of the comet on May 24, 1910; this value was obtained from measurements of the displacements of the Fraunhofer lines, and agrees, within 1 km., with the value given by the ephemeris.

Dr. Slocum described the spectroscopic effects produced by the large solar prominence of October 10, 1910. The prominence rose to a height of 105,000 km., and the local relative displacement of the absorption and emission lines represented a radial velocity of 15 km. per sec. Dr. O. J. Lee finds that, for reversal, the lines λ 4427 and H (λ 3968) require vapour densities one-seventh and 1·5 times as great, respectively, as that necessary for the reversal of K, when the vapour is observed at 2500° C. and at atmospheric pressure.

Prof. S. I. Bailey discussed the magnitudes of the stars in the cluster Messier 3, the discussion being based on a photograph, taken by Ritchey with the 60-inch reflector, showing some 30,000 stars down to magnitude 21·5: the total light of 2542 stars the magnitudes of which were determined is approximately equal to that of a star of magnitude 10·4. Dr. Albrecht reported on his work in determining the effective wave-lengths of lines in various types of stellar spectra, and also reported the results secured in a determination of the definite wave-lengths of the silicon lines at $\lambda\lambda$ 4552·7, 4567·9, and 4574·9 in stellar and in laboratory spectra. His stellar values are 4552·762, 4567·967, and 4574·918 respectively, and these are compared with similar values obtained by Gill and McClean, and laboratory values secured by Exner and Haschek, Frost and Brown, Lockyer, and Lunt. He emphasises the necessity for more laboratory work in order to investigate the causes producing the present lack of close agreement. In a third paper the same worker directs attention to the grave importance of investigating the change of wave-length of fundamental lines in passing from one spectral type to another. Such differences might, *inter alia*, account for certain systematic errors in the wave-length of the B type stars, and the elimination of these errors might directly affect the position of stars of this type in any discussion of the structure of the universe.

The list of papers concluded with one by Dr. Russell dealing with the photographic determination of the moon's position, a note on the five Ellicott astronomical instruments which were constructed about 1780–90 and are now on view in the U.S. National Museum, and a report from the committee on photographic astrometry. The resolutions of the latter strongly express the opinion that photographic methods can be applied successfully to absolute, as well as to differential, determinations of star positions, thereby gaining the advantage of independent observations with instruments of entirely different characters.

BIOMETRICIANS AS ANTHROPOLOGISTS.

IT is only necessary to turn to the current issue of *Biometrika* [1] to see the extent to which modern biometricians are devoting themselves to anthropology. About two years ago Dr. Crewdson Bennington died, leaving behind him a mass of observations and notes he had made in connection with the biometrical laboratory of University College. Prof. Pearson has systematised Dr. Bennington's observations and notes, and with the help of other workers in his laboratory brought Dr. Bennington's work to completion.

Dr. Bennington's aim was to obtain type-contours of the skull and of the living head of various races of mankind—contours which might serve as racial types. For instance, exact tracings were made in three planes of 100 crania of ancient Egyptian men. These contours were plotted out and combined by a method suggested by Prof. Pearson, and in this manner type contours were obtained for the ancient Egyptians of the twenty-sixth and thirtieth dynasties.

The results which interest us most are those contours prepared from the Whitechapel plague-pit skulls (seventeenth century) and those made from the heads of 118 men of the Royal Engineers of the present day. When these ancient and modern forms are compared, Prof. Pearson finds that there is no reason to believe that there is "any substantial difference between the English head of to-day and our plague-pit crania, which we have been told are not typical English." The editor of *Biometrika* has issued with this paper copies of Dr. Bennington's type-contours on transparent paper, so that they can be utilised by other workers for purposes of comparison.

Besides the important paper just noted, in parts i.–ii. of *Biometrika* there are others which will prove of value to the student of mankind. Dr. David Macdonald's inquiry seems to show that the acute infections of childhood favour the children with dark skin and eyes; they survive the effects of infection better than children with fair skin and blue eyes; the dark-skinned children are therefore being preserved or selected. Dr. Schuster's observations on the undergraduates of Oxford show that the students there have longer and narrower heads than those at Cambridge or at Aberdeen. The Oxford men are also considerably taller. Another important anthropological paper in the same number is Mr. J. I. Craig's "Anthropometry of Modern Egyptians."

ROCK CRYSTAL: ITS STRUCTURE AND USES.[2]

ROCK crystal, quartz, the common crystallised form of dioxide of silicon SiO_2, is, from many points of view, the most interesting of all minerals and the most instructive example of crystalline structure known to us. "What is a crystal?" The evidence is now overwhelmingly complete that a crystal is a homogeneous structure built up on the plan of a space-lattice, each of the unit

[1] *Biometrika*, parts i. and ii., July, 1911. Edited by Prof. Karl Pearson. Price 20*s*. net.

[2] From four Cantor Lectures delivered in May, 1911, to the Royal Society of Arts by Dr. Alfred E. H. Tutton, F.R.S.

cells of which is the habitat of a chemical molecule of the substance of which the crystal is composed, and of which it is the most highly organised solid form. It was shown by Frankenheim and Bravais that there are fourteen such space-lattices possible, all of which exhibit the full symmetry of one or other of the seven crystal systems, the cubic, trigonal, tetragonal, hexagonal, rhombic, monoclinic,

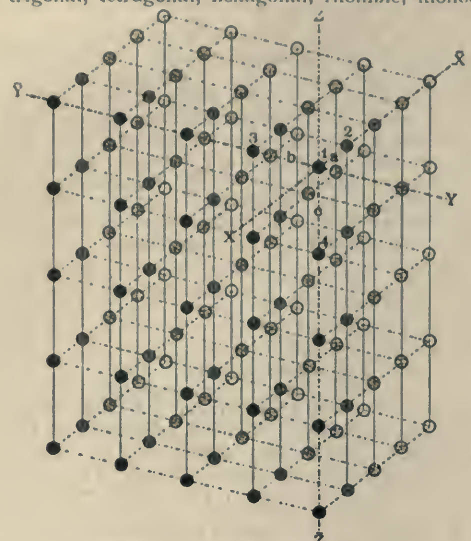


FIG. 1.—Triclinic Space-lattice.

or triclinic. As a typical example of a space-lattice, and the one of most general form, the triclinic space-lattice is shown in Fig. 1.

But the chemical molecules, the arrangement of which thus determines the crystal system, are not the ultimate units, being composed of elementary atoms, and it is the arrangement of these latter, the ultimate structural units, which determines the class of the system.

Quartz crystallises in the trigonal system of symmetry. It does not develop, however, the full holohedral trigonal symmetry, but that of the trapezohedral class of the system, no plane of symmetry being present, and the three digonal axes of symmetry occupying positions in the horizontal plane midway between those of the holohedral class.

Now in the most general case six faces are required to be present by the symmetry elements in operation, when one face is given as present, and they make up a double

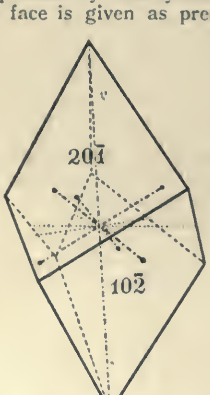

FIG. 2.—Right Trigonal Trapezohedron.

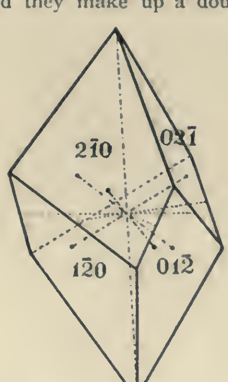

FIG. 3.—Left Trigonal Trapezohedron.

trigonal pyramid, of which the lower half is rotated somewhat with respect to the upper, screw-wise, the solid thus produced being known as a trigonal trapezohedron.

In actual fact two such trigonal trapezohedra, which are the mirror-images of each other, are possible, and the two solids are quite distinct, for no amount of rotation will bring either to resemble the other. That corresponding to Fig. 2 is called the right trigonal trapezohedron, and that represented by Fig. 3 the left variety. This fundamental fact respecting the general form of this class of trigonal symmetry affords the explanation of the two varieties, right- and left-handed, of quartz, which mineral shows characteristic development, in the well-known little *x* faces, of the two trapezohedra.

Two characteristic crystals of quartz, a right-handed and a left-handed one, are shown in Figs. 4 and 5, on which the small faces *x* are those of the right and left trigonal trapezohedra respectively. Also, the little adjoining faces *s* are those of another pair of mirror-image complementary forms of the trapezohedral class of trigonal symmetry, the right and left trigonal bipyramids. The other faces shown on Figs. 4 and 5 are those of the hexagonal prism *m*, a form common to both the hexagonal and trigonal systems, and also common to both varieties of crystals of the trigonal trapezohedral class; also those of the two complementary rhombohedra *r* and *r'*, which together make up what appears to be the hexagonal pyramid terminating each end of a fully-developed quartz crystal. Alternate faces of the pyramid belong, however, to different rhombohedra, three to *r* and three to *r'*; and they are often characteristically different, either in amount of development or in polish, the faces of the rhombohedron *r* being much more brilliant than those of *r'*. Moreover, the quartz crystals from a particular locality in Ireland show one rhombohedron only, without a trace of the other.

It will be observed, further, that the little *s* and *x* faces occur replacing right solid angles on a right-handed crystal, and left solid angles on a left-handed crystal. Also, if *x* faces be absent, a good little *s* face is often present, and

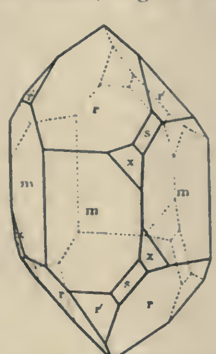

FIG. 4.—Right-handed Quartz.

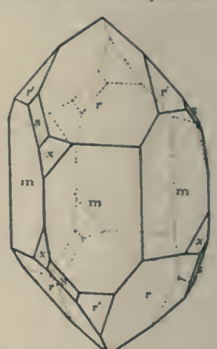

FIG. 5.—Left-handed Quartz.

it is usually marked by striæ parallel to the edge *sr*, which enable the location of the face, and its nature, to be recognised.

We are next attracted by the further problem of the internal structure, which is the prime cause of this outward development. The evidence afforded by cleavage is very emphatic, in spite of the fact that quartz cleaves only with the greatest difficulty. Indeed, this difficulty of provoking cleavage in quartz enhances wonderfully the importance and use of the mineral, both for scientific and industrial purposes, for it enables lenses, prisms, and plates of this clear, transparent mineral to be cut, ground, and polished with the greatest ease, without risk of flaw. But when a quartz crystal is heated, and then suddenly cooled by plunging it into cold water, it breaks up into rhombohedra closely resembling cubes, the angle of which is 85° 46', that of the primary rhombohedron *r* of Figs. 4 and 5. Now it is interesting, also, that simple apparent cubes, really these rhombohedra, of quartz are occasionally discovered, quite a number having been found in the neighbourhood of Bristol.

These facts not only confirm the trigonal, as distinguished from possible hexagonal, symmetry of quartz, but also indicate that the space-lattice structure present is that of the rhombohedron, the elementary cell of which is represented in Fig. 6.

Thus we conclude that if each molecule SiO_2 were represented by a point, the points would be arranged in the form of a rhombohedral space-lattice having the angle of the rhombohedron of quartz, 85° 46'.

If we take, next, a hexagonal section of a prism of

quartz and heat it gently and evenly over a small Bunsen flame or other source of heat, and then allow it to cool, electrical excitation is developed, positive and negative electricity being produced, respectively, at alternate corners of the hexagon. Now the three digonal axes of symmetry emerge at the six corners, and the little trigonal pyramid and trapezohedron faces *s* and *x* are present at alternate corners corresponding to one end only of each axis; and it is interesting that these corners where the little distinctive faces are present are those which become negatively electrified, while those corners where no *s* and *x* faces are developed become positively electrified. This disposition of the pyroelectric poles is precisely in accordance with the symmetry of the trapezohedral class of trigonal symmetry.

If we treat a pair of quartz crystals, right- and left-handed respectively, with a small quantity of aqueous hydrofluoric acid, a chemical solvent for silica, characteristic little markings, or "etch-figures," are produced on the faces. They are little depressions, of the shape of a candle flame blown to one side by a draught of air, to the right on a right-handed crystal and to the left on a left-handed crystal, and are pointing upwards and downwards, respectively, on alternate faces. Thus we have trigonal rather than hexagonal symmetry again demonstrated, and a screw structure, clockwise in one variety and anti-clockwise in the other, such as corresponds to the trapezohedral class of the trigonal system, also most clearly indicated.

Now it has been definitely proved that specific atoms of the chemical molecule are definitely orientated in the crystal, and that if such atoms, say those of potassium or of sulphur in potassium sulphate, be replaced by others of the same family group of chemical elements, for instance, the potassium by rubidium or cæsium, and the sulphur by selenium, specific directional changes in the crystal angles are observed to occur. In the cases just referred to, the replacement of the metal brings about an alteration in the length of the vertical axis of the rhombic crystal of the sulphate or selenate, while replacement of the sulphur by selenium causes an equatorial change. If, therefore, we accept the view of Barlow, and represent the atoms by their spheres of influence, we are only logically following up this important experimental fact.

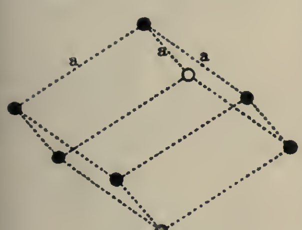

FIG. 6.—Unit Cell of Rhombohedral Space-lattice.

Barlow has recently propounded the view, in collaboration with Pope, that the relative size of the sphere of influence of an atom in any one compound, compared with that of any other atom in the same compound, is intimately connected with the chemical valency of the element, being proportional to the fundamental valency. This is rarely the maximum valency, although in the case of carbon it would appear to be so, atomic spheres of influence of carbon having apparently four times the volume of those of hydrogen or chlorine present in the same compound. The relative size of the atomic sphere of influence of oxygen appears to conform to its usual dyad character. Silicon might, perhaps, from its occurrence in the same family group of elements as carbon, be expected to behave also as a tetrad, but there is much more evidence that its fundamental valency is only dyadic. Now Barlow has shown that if we accept the view that the fundamental valencies of both silicon and oxygen are dyadic, and therefore that the spheres of influence of the two elements in quartz are of the same size, the whole of the properties of quartz can be explained on the assumption that the two structures, right-handed and left-handed, are composed of such assemblages as are shown in Figs. 7 and 8, in which the white spheres represent silicon and the black ones oxygen atoms, there being two of the latter to every one of the former, corresponding to the formula SiO_2.

The helical character is clearly shown by these assemblages of silicon and oxygen atoms, the white spheres of the former being obviously arranged in a right-handed screw in Fig. 7 and in a left-handed helix in Fig. 8, the two arrangements being the mirror-images of each other, as a right-hand glove is to a left-hand one. That some such structural arrangements of the chemical atoms as these are really present in the two varieties of quartz is, indeed, highly probable

The most important and convincing evidence of the right- and left-handed screw structure of quartz is afforded, however, by the optical properties of the mineral.

We may study, first, the effect of passing the light from the lantern, an image of a slit in front of which is focussed on the screen by a lens, through either of two 60° prisms, one cut so that the light passes through the crystal at minimum deviation parallel to the axis, as shown in Fig. 9, and another with the refracting edge parallel to the axis, as shown in Fig. 10. In the latter case we see two spectra on the screen, which are separately extinguished by a large Nicol prism placed in the path of the rays, when rotated to two positions 90° apart; while in the former case only a single spectrum is produced on the screen, and remains permanent when the Nicol is placed in position and rotated, just, in fact, as if the quartz prism were made of glass. This is the mode of cutting quartz prisms employed for use in experiments with ultra-violet light, such as the investigation of the ultra-violet spectrum, quartz being remarkably transparent to these ultra-violet rays of short wave-length, which are entirely cut off by glass.

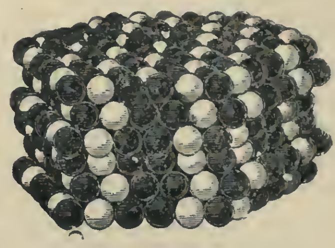

FIG. 7.—Barlow's Conception for Right-handed Quartz.

FIG. 8.—Barlow's Conception for Left-handed Quartz.

We may next investigate plates of quartz in polarised light. Placing a plate of quartz 1 millimetre thick in the polariscope arranged for convergent light, we perceive a more or less normal uniaxial figure, although the rings are large and diffuse and the dark cross present is also very diffuse. If we now take a thicker plate, conveniently one 3·75 millimetres thick, the coloured rings are more numerous, the innermost being smaller; the arms of the cross are also sharper near the margin of the field, but they have entirely disappeared from the centre of the figure, and the whole of the interior of the innermost ring is filled instead with yellow light. Moreover, if we rotate the analysing Nicol clockwise, this ring expands if the plate has been cut from a right-handed crystal of quartz, but contracts if the crystal be a left-handed one, the circular nature of the ring also altering until it is nearly square. If, now, we superpose two such plates 3·75 millimetres thick, one of right-handed quartz and the other of left-

FIG. 9.—60° Prism Cut for Light to Traverse Axis.

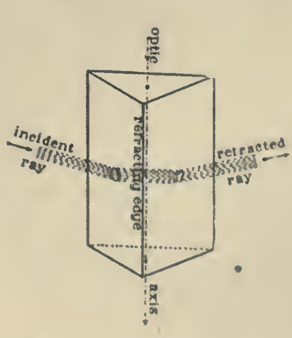

FIG. 10.—60° Prism with Refracting Edge Parallel Axis.

handed, we obtain a remarkable change in the figure, namely, the production of the celebrated spirals of Airy.

Now these phenomena suggest a spiral, and a complementarily helical, arrangement of the atoms composing the chemical molecules of silica in the two forms of quartz crystals. That the supposition is correct may be proved, as first shown by Reusch, by reproducing the effects by means of a spirally arranged pile of biaxial mica films. Twenty-four equally thin films of ordinary muscovite mica are laid over each other so that the direction of the line joining the two optic axes of the mica regularly rotates by the same angle, conveniently 60°. The biaxial figure normally given by muscovite mica will be found, on placing the pile in the polariscope, to have been converted into a uniaxial one. Moreover, the figure resembles that afforded by quartz to a remarkable degree of precision, for if the pile be a right-handed one the figure is similar to that afforded by right-handed quartz, and gives the same effects on rotating the analyser; whereas, if the pile had been arranged in a left-handed manner, the effects would resemble those afforded by a plate of left-handed quartz. Further, if we superpose the two piles of mica plates, the left-handed and the right-handed, and place them together in the polariscope, Airy's spirals are at once produced on the screen.

Let us now study quartz plates in a parallel beam of polarised light. If we take two plates, one of right-handed quartz and the other of left-handed, each of 7·5 millimetres thickness, we find that they each give with crossed Nicols the well-known rose-violet tint of passage between the first and second orders of Newton's spectra. But on rotating the analysing Nicol clockwise, the right-handed plate changes colour first to red, then to orange, yellow, green, and blue, while the left-handed plate becomes first blue, then passes through green and yellow to orange and red.

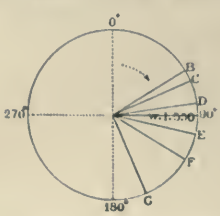

FIG. 11.—Rotations by 3·75 mm. of Quartz.

FIG. 12.—Rotations by 7·5 mm. of Quartz.

On the other hand, the two plates of 3·75 millimetres thickness appear yellow under crossed Nicols, just as were the centres of the interference figures in convergent polarised light, and they change colour in opposite directions of the spectrum on rotating the analyser, until they become violet with the tint of passage when the Nicols are parallel.

Now all these beautiful phenomena are due to the fact that when a beam of light is sent along the axis of a quartz crystal, the right- or left-handed arrangement of the molecules of silica causes the plane of vibration of the polarised light received from the polarising Nicol to be rotated in the same direction, the amount being directly proportional to the thickness of the plate. It also varies considerably with the wave-length of the light. For plates of 3·75 and 7·5 millimetres thickness, respectively, the rotations by plates 1 millimetre thick are indicated in Figs. 11 and 12. Fig. 11 shows that the plane of vibration of yellow light of wave-length 0·000550 is rotated just 90° by a plate of 3·75 millimetres thickness, and this explains the production of the violet tint of passage when we have rotated the analysing Nicol 90°, that is, until it is parallel to the polarising Nicol. For the extinction of this yellow light leaves the complementary colour, the violet transition tint, predominant. And when we double the thickness of the plate to 7·5 millimetres, the yellow ray, of 0·000550 millimetre wave-length, is rotated just 180°, as shown in Fig. 12, which, when followed (by rotation of the analyser), brings the Nicols into the crossed position again, and thus the violet transition tint is at once given by such a plate under crossed Nicols.

The colour produced by thick plates of quartz in polarised light is thus due to optical rotation, and it is quite as brilliant as that due to double refraction shown by thin plates of quartz, such as those of rock-sections, which vary from a twenty-fifth to a fiftieth of a millimetre in thickness. The phenomenon of optical activity is confined to crystals belonging to those eleven classes of symmetry which exhibit right- and left-handed forms, that is, in which there is no plane of symmetry developed.

Now besides the right- and left-handed forms, showing dextro and lævo rotation, chemists have discovered many cases in which the optical activity is either neutralised or destroyed by intimate lamellar twinning of the two complementary varieties, or by chemical combination of the two sets of molecules in which the atoms are oppositely spirally arranged. In the former case of regularly repeated twinning the symmetry is apparently enhanced by the introduction of a plane of symmetry, the composite crystal showing the characteristic faces of both right- and left-handed forms. In the latter case chemical combination results in the production of a new substance, and the crystalline form is altogether different, and may even belong to another system. This is the case with tartaric acid, for the combination of the two sets of molecules produces racemic acid, which crystallises in the triclinic system with a molecule of water of crystallisation, totally unlike the crystals of either ordinary dextro (right-handed) tartaric acid or the complementary lævo (left-handed) tartaric acid, both of which belong to the sphenoidal class of the monoclinic system, and are anhydrous.

Now the racemic form of optical inactivity is often

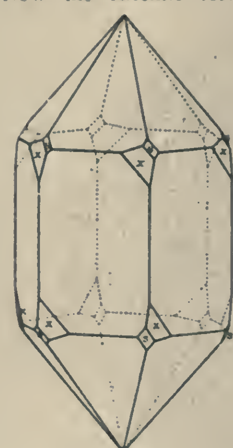

FIG. 13.

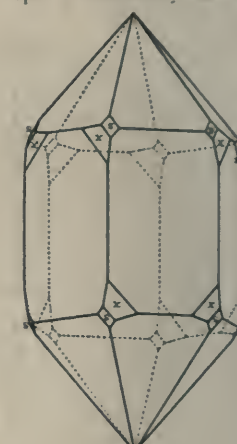

FIG. 14.

The Two Types of Quartz Twins.

simulated to a most remarkable extent by the repeated twinning already referred to; but such a "pseudo-racemic" form can generally be readily distinguished from a truly racemic form by the fact that it still exhibits the symmetry of the same system, although that of a class of higher symmetry in the system, owing to the introduction of a plane of symmetry, about which the twinned individuals are disposed in mirror-image fashion. This case of the mechanical enhancement of the symmetry by repetition twinning is beautifully illustrated by quartz, especially in the exquisite form of the mineral known as twins, one, illustrated in Fig. 13, in which the two individuals are of the same right- or left-handed variety, and another, represented in Fig. 14 by an example in which also complete interpenetration has occurred, in which a right-handed crystal is twinned with a left-handed one.

This latter kind of quartz twin is frequently found occurring among specimens from Brazil. The twin plane is a face of the hexagonal prism of the second order, perpendicular to a pair of the faces of the hexagonal prism present, which is of the first order. The little *s* and *x* faces are shown on every corner, as in the case of Fig. 13, but symmetrically.

Now if a plate of such a crystal be cut perpendicularly to the axis, the polarisation phenomena, due to the opposite optical activity of the two different varieties present, will vary according to their mode of internal disposition. When the whole of one half of the crystal is of right-handed and the other of left-handed quartz, and the surface of junction is a plane parallel to the axis, we have a natural biquartz

produced on cutting such a section-plate which shows absolutely no trace of a junction-plane in ordinary light or when the Nicols are crossed or parallel, but exhibits different colours in the two halves the moment either Nicol is rotated to even the slightest extent.

If the plane of junction be oblique, however, the biquartz shows a black band between the two halves when the Nicols are crossed, and a white one when they are parallel, as in the case of a natural biquartz projected on the screen, the obliquity of the junction plane in which is not great. When the junction-plane is of greater obliquity, not only the central black band, but a white one and a spectrum on each side of it, are exhibited, as illustrated on the screen by an example.

A very instructive case is that of a natural quartz twin-combination, which by its picture on the screen in polarised light, illustrated in Fig. 15, is seen to be composed of one half of left-handed quartz, which polarises in a rich crimson lake with crossed Nicols, and a second half which is made up of alternating right- and left-handed quartz, the strips being joined obliquely to the plate, so that a black band is produced in each case as the central line of a ribbon, being flanked by a white band and a spectrum band on each side.

Such a banded structure of alternately right- and left-handed quartz affords an instance on a larger scale of the finely laminated twinning of the two varieties present in amethyst. The case of a section-plate of amethyst is an exceedingly beautiful one. The marginal parts show polarisation colours in three sectors, indicating the presence of right- or left-handed quartz. The alternate sectors, however, show a natural violet colour, which is the distinctive feature of most amethysts: hence the name; and in the central part of the plate these sectors exhibit the beautiful laminated twinning effect, under crossed Nicols a delicate slate-coloured line marking the junction of each pair of right and left laminæ, each lamina itself appearing as a thin white band bordered by traces of spectra. On rotating the analysing Nicol the laminæ exhibit the most beautiful shades of greys and browns, with delicate linings of rose and other tints. This central part of the plate, moreover, is unique among quartz crystals in exhibiting a normal uniaxial interference figure in convergent polarised light, that is, with the black cross complete to the centre.

FIG. 15.—Banded Quartz Twinning.

Thus the intimate lamellar twinning of the two varieties of quartz in amethyst results in the production of a crystal which simulates holohedral trigonal symmetry, and is apparently optically inactive, the optical activity of the lower-class pair of varieties being neutralised by their intimate blending. Amethyst, therefore, is not a case of true optical inactivity, but of mechanically and naturally produced pseudo-inactivity. It is thus an excellent illustration on a large scale of the still more intimate blending of microscopic or even submicroscopic laminæ of the two varieties in the organic substances known to chemists as pseudo-racemic compounds, a large number of which have been studied by Kipping and Pope. In many of these cases the blending of the two varieties by regular intercalation and alternation of the two varieties, one within the other, is so intimate that the laminæ approach the molecular dimensions in thinness. It is easy to see that if the approach be continued until this fascinating region of molecular forces be penetrated—for we know that within four or five molecular diameters these intermolecular forces come into play—chemical affinity will be developed with the production of a molecular compound—a racemic compound—of the two varieties, the individuality of each variety being no longer preserved, but a new compound, due to the double molecule, being produced and crystallographically developed according to its own crystalline form.

The investigation of the twinning of quartz, as seen in its most beautiful development in amethyst, has thus enabled us to elucidate some of the most interesting and complicated phenomena of optical rotation and of chemical crystallography.[1]

THE VALUE OF BIRDS TO MAN.[2]

VEGETATION is the prime requisite for the perpetuity of all other forms of life upon the earth. The greatest known enemy to vegetation is insect life, while bird life, by virtue of its predominating insect diet, wields a most important balance of power against the ravages of this the chief pest of vegetation.

The number of insect species is greater by far than that of the species of all other living creatures combined. The voracity of insect life is as astonishing as its power of reproduction. Many caterpillars consume twice their weight in leaves per day, which corresponds to a horse eating daily a ton of hay.

The development of young birds is so rapid, and the demand upon the vitality of older ones so great, that an enormous amount of food is necessary to sustain the vital processes. Digestion is exceedingly rapid in birds; and they feed for the most part throughout the day, especially when rearing young. The number of insects daily passed into the insatiable maws of the nestlings during this period almost exceeds belief. But the most valuable services of the adult bird are rendered when it is feeding in winter or early spring, for then it destroys countless numbers of insects in the embryo state, and thus prevents myriads of depredators from coming forth. Grave and far-reaching results invariably follow the suppression of this perennial regulative influence which is exerted by birds individually everywhere as a check on insect life.

Forest trees have their natural insect foes, to which they give food and shelter; and these insects in turn have their natural enemies among the birds, to which the tree also gives food and shelter. Birds are not only essential to the well-being of the tree, but the tree is necessary to the life of the bird. It is because of this most delicate adjustment between the tree, the insect, and the bird that Mr. Frank M. Chapman's statement "that it can be clearly demonstrated that if we should lose our birds we should also lose our forests," must be regarded as profoundly true. Call the bird in the orchard an evil if you will. But it is a necessary evil, and the fruit-grower must make up his mind to pay the bird its wages, even though at times they may seem exorbitant.

Each season, until hay-making commences, the grass offers cover and shelter for the nests of such birds as breed on the ground. The fields also provide food for birds, and for the insects on which birds feed. Where the birds of the field are undisturbed they tend to hold the grass insects in check. On the other hand, when the numbers of birds in the field are, for any reason, insufficient, the insects increase.

Without birds grass could not be grown. The grub of a single species of beetle, if unchecked, could destroy all the grass roots of our meadows, or any one of the several

[1] The concluding lecture, which concerned the scientific and artistic uses of quartz, does not lend itself to abbreviation, and for an account of it the Journal of the Royal Society of Arts of October 27 (vol. lix., p. 1091) should be consulted.

[2] From a paper read before the British Empire Naturalists' Association on December 1 by James Buckland.

species of cut-worms might be sufficient to destroy all the verdure above ground.

The destructive habits of the small rodents, which are the natural prey of hawks and owls, are much the same all the world round. Here in England—though on account of their small size and secretive habits they are often undiscerned by man's dull eyes—they swarm in such numbers in the fields and hedgerows that the damage they do must prove a steady drain on the resources of the farmer. The number of small rodents eaten by the rapacious birds is almost as remarkable in proportion to their size as is the number of insects eaten by small insectivorous birds.

The young of hawks and owls remain a long time in the nest, and require a great quantity of food. During this period the resources of the parents must be taxed excessively in the effort to satisfy the hunger cravings of their offspring, and it is not to be wondered at if some individuals are forced occasionally to snap up a chicken. But what is the worth of the chicken, or of the young pheasant, occasionally taken compared with the hundreds of thousands of pounds' worth of damage that is wrought in the orchards and fields by rodents that hawks and owls, had they been spared, would have fed upon for the maintenance of their species?

The destruction of the white heron for its scapular plumes has robbed half the world of a bird which is most useful to man. Its loss to India and to China is most serious. It never touches grain, but feeds solely near water and over damp ground, the breeding-places of innumerable batrachians, small crustaceans, and pestiferous insects, all of which directly or indirectly injuriously affect crops in the neighbourhood. The presence of the white heron in the rice-fields, for instance, is distinctly beneficial to the farmer, and rice is one of the most extensively grown crops of India and of China.

Turning to Australia, it may be mentioned that the slaughter of this and other wading birds for their plumage is causing in that country a decline in its fish resources. As these birds grow fewer in numbers, so do the crustaceans that destroy the fish spawn increase in hosts.

The gull is a surface feeder. It may occasionally levy toll on useful fish when they are indiscreet enough to come to the surface of the water, but to say that they do any appreciable injury to the fishery business is absurd. On the other hand, the presence of the gull is essential to man's health. While the bird fulfils many useful minor offices, such as destroying larvæ in land along the seaboard, and in eating enemies of fish that are exposed during low tide, its chief function in the economy of nature is that of scavenger of the harbours and of the littoral, just as vultures are the scavengers of the mainland.

Birds, unquestionably, are one of man's greatest possessions; yet it is just the possession on which he often sets the least value.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—At the meeting of the Senate on December 13 an anonymous gift of 30,000*l.* was announced, to be devoted to the erection at University College of the buildings for the new School of Architecture, resulting from the amalgamation of the architectural department of University College and King's College. Any balance is to be used for providing studios for the teaching of sculpture and the rearrangement of the School of Fine Art and for the Department of Applied Statistics, including the Laboratory of Eugenics. The gift was accepted by the Senate with cordial thanks. The frontage of the new building will be towards Gower Street; and it is expected that the new building, together with the new chemical laboratories, which will be to the north of the college, will much improve the architectural effect of the college buildings.

OXFORD.—The following lectures and practical courses, in addition to those already noticed in NATURE, have been announced for next term, beginning on January 22, 1912. In human anatomy, Prof. A. Thomson will lecture on joints and the muscles which move them, and will give special demonstrations. Demonstrations will also be given by Messrs. Whitnall and Foster. Mr. Dodds-Parker will lecture on the thorax, and Mr. Doyne on the human eye. In the department of comparative anatomy, Prof. Bourne, F.R.S., will lecture on the Echinodermata and on principles of zoology; Mr. E. S. Goodrich, F.R.S., on the general morphology of Vertebrata, Amphibia, Reptilia, and Aves; Mr. G. W. Smith, on elementary zoology. Practical instruction will be given by the professor, assisted by Messrs. Smith, Huxley, and Coventry. Dr. Jenkinson will lecture on the embryology of Chordata and on regeneration. Prof. Gotch, F.R.S., will continue his general course of physiology, and will give advanced lectures on the excitable phenomena of nerve. Dr. Haldane, F.R.S., and Dr. Ramsden will lecture on subjects of the Final Honour examination in physiology; and practical instruction, elementary and advanced, will be given by Dr. Scott, Dr. Vernon, Dr. Ramsden, and Dr. Douglas, together with the professor; the subjects specially dealt with being histology, muscle and nerve, and physiological chemistry.

Prof. Sollas, F.R.S., will give a general course on geology, and will lecture specially on the geology of Europe. Mr. Vaughan will lecture on palæontology and evolution. Prof. Vines, F.R.S., will give courses on botany for students of forestry and agriculture respectively, and a preliminary course for elementary students. Practical instruction at the Botanic Garden will be given by Dr. Church and Mr. Hiley. Prof. Somerville, F.R.S., will lecture on the principles of agriculture and on forest botany, Mr. Curtler on the history and economics of agriculture, and Mr. Morison on agricultural chemistry. Prof. Odling, F.R.S., will lecture on organic chemistry: uric acid and products; Dr. Watts on organic chemistry: terpenes and camphors. Mr. Marsh will continue his course on the history of chemical theory, and Mr. Fisher will lecture on the subjects of the Preliminary examination in chemistry. Dr. Baker, F.R.S., will lecture at Christ Church on the chemistry of the metals. Prof. Bowman and Mr. Barker will lecture and give practical instruction on elementary crystallography and mineralogy.

Lectures will be given and practical work conducted in geography by Prof. Herbertson, Mr. Beckit, Miss MacMunn, and Mr. Crawford. Dr. Grundy will lecture on the historical geography of Greece, and Mr. Munro on that of Canada. Mr. Mackenzie will give advanced instruction in surveying. Mr. Knowles will superintend instruction in physical anthropology, Dr. Schüster will lecture on statistical methods in anthropometry, Mr. H. Balfour on comparative technology, and Mr. Marett on social anthropology. Sir W. Schlich, F.R.S., will lecture on forest valuation and forest management, Mr. Caccia on sylviculture and forest protection, and Mr. Grosvenor on forest zoology.

DR. A. D. IMMS, professor of biology, University of Allahabad, has been appointed forest zoologist to the Government of India, Forest Research Institute, Dehra Dun, United Provinces.

PROF. HENRI BERGSON, professor of philosophy of the Collège de France, has accepted the invitation of the Senatus Academicus of the University of Edinburgh to be Gifford lecturer from October, 1913, to October, 1915.

IT is announced in *Science* that formal distribution has been made of the California property of the late Mr. D. O. Mills. Among other bequests we notice the following:—the American Museum of Natural History, 20,000*l.*; the New York Botanical Garden, 10,000*l.*; and the American Geographical Society, 5000*l.*

A NOTE in *Science* states that the registration of students in several of the larger universities is reported to be as follows:—Columbia, 7429; Chicago, 6466; Minnesota, 5965; Wisconsin, 5538; Pennsylvania, 5389; Michigan, 5381; Cornell, 5104; Illinois, 5118; Harvard, 5028; Nebraska, 4624; California, 3450; and Missouri, 3141.

THE council of Bedford College for Women (University of London) has received donations and promises to the building fund amounting to 8285*l.* This leaves only 1715*l.* to be collected to enable the college to claim the additional grant of 10,000*l.* promised by the London County Council when the fund reaches 60,000*l.*

The council urgently appeals for this balance of 1715*l.* on the further ground that if it is obtained before January 1, 1912, Sir Francis Trippel has undertaken to raise the remaining 30,000*l.*, which will complete the building and endowment scheme.

WE learn from the annual report and statement of accounts for the year 1910–11 of the Livingstone College that it has been decided to inaugurate a Livingstone Centenary Fund in connection with the centenary of the birth of Dr. Livingstone, to take place in 1913. It is proposed to devote the fund to the paying off of the mortgage on the property, the carrying out of certain important improvements in the college premises, and the raising of an endowment. Livingstone College, it will be remembered, was instituted with the object of preparing missionaries and providing them with an elementary medical training.

The fourth annual dinner of old students was held on December 13 in the new Imperial College Union in Prince Consort Road, this being the first occasion on which the new club has been used for such a purpose. Sir Alexander Pedler, president of the Old Students Association, presided, and Mr. J. A. Pease, the President of the Board of Education, was the guest of the evening. In proposing the toast of "The College," Mr. Pease referred to the large number of students who have passed through the college, many of whom are occupying positions as chemists, geologists, engineers, and Government officials, and are doing excellent work. Prof. W. W. Watts, in responding, referred to the relationship between the Royal College of Science, the Royal School of Mines, and the City and Guilds College under the new organisation, and expressed the hope that each will retain its individuality. Prof. Dalby, Dean of the City and Guilds College, proposed the toast of "The Old Students Association," to which the chairman replied. The guests included the Rt. Hon. A. H. D. Acland, Sir Alfred Keogh, Sir Arthur Church, and Prof. Cox.

IN his annual report for the year ending on June 30 last, President Butler, of Columbia University, in New York, summarises the benefactions received during the year by the University over which he presides. The gifts, legacies, and other receipts for designated purposes received during the year amounted to 507,000*l.* Of this great sum, 195,000*l.* was in partial payment of the legacy of the late Mr. J. S. Kennedy, and 138,700*l.* in partial payment of the legacy of the late Mr. G. Crocker. Toward the erection of the philosophy building 33,000*l.* was received from an anonymous donor. Other anonymous gifts of 20,000*l.* and 11,000*l.* were received. Including the gifts to Barnard College and to Teachers College, both of which are associated with the University, the sum total of benefactions for the year very nearly reached 600,000*l.* The grand total of gifts in money alone made to the several corporations included in the University during the last ten years reaches 3,310,000*l.* As indicative of the growth of the University during these ten years, it is interesting to note that while in 1901 the number of professors was 81, in 1911 it has reached 177. In 1901 there were 396 teachers of all grades, but during the present year the number has been 721.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, December 6.—Prof. W. W. Watts, F.R.S., president, in the chair.—Dr. T. F. **Sibly**: The faulted inlier of Carboniferous Limestone at Upper Vobster (Somerset). The Upper Vobster inlier lies rather less than a mile to the north of the main outcrop of the Carboniferous Limestone of the Mendips. This inlier has been dissected by quarrying operations. The northern and eastern portions are concealed by a covering of Lias, but its width from north to south is little, if at all, greater than 400 yards, while the east-and-west extent of the Carboniferous Limestone is about 1100 yards. The author has arrived at the following conclusions:—The inlier is a lenticular mass of Carboniferous Limestone, grits, and shales, superimposed upon the overfolded strata of the Coal Measures by thrust-movements. It comprises a northern limestone mass and a southern limestone mass, separated by a grit-and-shale mass. The beds of the grit-and-shale mass are in faulted relation to the Carboniferous Limestone. On the northern side, the adjacent beds of limestone represent part of the Seminula zone; on the southern side, the adjacent beds belong to the lower Dibunophyllum zone. In the northern limestone mass, Vobster Quarry exposes more than 500 feet of Seminula beds, overfolded towards the north-west. In the southern limestone mass the strata are locally overfolded northwards. The beds of the grit-and-shale mass comprise quartzites assigned to the Millstone Grit. They also include shales, with intercalated fine-grained sandstones. Possibly this mass includes the lowest beds of the Coal Measures, in addition to a portion of the Millstone Grit. In sections of Carboniferous Limestone, signs of the stresses to which the strata have been subjected are evident. The beds are often distorted, while slickensides and calcite-veins are developed. The occurrence of a lamellibranch fauna at the top of the Seminula zone is recorded.—J. **Romanes**: Geology of a part of Costa Rica. The part of Costa Rica to the west of San José as far as the Pacific coast is dealt with. San José is situated in a valley sloping westwards, and drained by the Rio Grande and its tributaries. The northern boundary of this valley is the chain of recent volcanoes which rise from its floor, while on the south the ground rises abruptly to form the Cerro Candelaria. In this range of mountains are exposures of limestone, marl, &c., together with igneous rocks. An examination of exposures has failed to produce any Cretaceous fossils, while the occurrence of numbers of Balani points to a Tertiary age for the beds. As this limestone stretches across the Atlantic-Pacific watershed, it yields evidence of an interoceanic connection in this area in Tertiary times. Of the igneous rocks, the most interesting feature is the presence of many boulders of monzonite, indicating a plutonic mass in these mountains. The surface of the valley is composed of a thick series of andesitic lavas. On the Pacific coast at Barranca and Manzanilla fossiliferous Tertiary beds are described. These are all marine ashes, and in the Manzanilla district appear to rest unconformably on an older limestone formation. The boulder-clays of Costa Rica are normal river deposits, though, locally, landslides and spheroidal weathering have played an important part.

Linnean Society, December 7.—Dr. D. H. Scott, F.R.S., president, in the chair.—H. N. **Dixon**: Some mosses of New Zealand. Several collectors had contributed to this account, and specially referred to the mosses sent by Mr. W. Gray from Mauriceville, Wairapa, North Island, which were of the highest interest. A new genus was named Tetraphidopsis, Broth. and Dixon.

Royal Astronomical Society, December 8.—Dr. F. W. Dyson, F.R.S., president, in the chair.—Miss Winifred **Gibson**: The errors of measurements on photographic plates. Measures were made with various orientations of the plate, and the results compared. It was concluded that unless a preliminary series of measurements were made, measures with four different orientations would be required, as maintained by M. Lœwy, in order to obtain trustworthy results.—F. Hope **Jones**: The synchronome astronomical regulator. The arrangement was exhibited and described. It consists of a free pendulum with detached gravity escapement, the impulse being given by a lever falling upon a wheel pivoted at the bottom of the pendulum, and reset by the "synchronome" remontoire action. The arc is maintained constant by an inertia device of Mr. Shortt.—H. H. **Turner**: The determination of differential star places by photographic methods. The selection was suggested of many consecutive regions of the same declination and hour-angle on the same plate, with considerable overlap. The present paper was restricted to the consideration of systematic errors, the main discussion of final places being reserved for a future communication.—Prof. **Fowler** showed photographs of the spectrum of comet Brooks, taken by Mr. Slipher at the Lowell Observatory, and of the spectrum of Morehouse's comet.—A fine series of photographs were also shown of comets Brooks and Beljawsky, taken at the Khedivial Observatory, Egypt, by Mr. Knox Shaw.—G. D. C. **Stokes**: A

critical comparison of the overlapping section of the Oxford and Potsdam Astrographic Catalogue. A number of plates covering the richest region of the zone were selected for examination, and forty stars distributed all over the overlapping area, but not too near the edges, were chosen. These stars were between 8·5 mag. and 10 mag., so as to be neither too bright nor too faint to give good images. Two systems for obtaining the required solutions were adopted and investigated, and the results compared, proper motions being taken into account. The author concluded that the astrographic errors must be ascribed as much to erroneous photographic places as to errors of meridian catalogues. The errors in right ascension were smaller than those in declination.

Royal Anthropological Institute, December 12.—John **Gray**: A new perigraph. In recent years anthropologists have come to the conclusion that one of the best methods of determining the racial affinities and differences of two skeletons is to compare the outlines of their skulls and other bones. It is necessary that these outlines should be exact orthographic projections, and for this reason photographs, taken by the ordinary camera, are unsuitable. Various special instruments, known as "perigraphs," have been devised, chiefly by Continental anthropologists, for drawing these outlines, among the best known of which are those of Martin, of Zurich, and Klaatsch, of Breslau. Most of these instruments suffer from certain defects. A new design has been introduced in the two forms of the perigraph, exhibited and described by Mr. Gray, in which advantage is taken of the well-known principle in mechanism that every point in a plate moving parallel to itself describes exactly similar curves. The application of this principle enables the outline to be drawn at one side instead of under or over the skull, and the delicate adjustments of tracer and pencil in the older instruments are rendered unnecessary. By an ingenious application of the stereoscopic principle, Mr. Gray is able in one form of his instrument to draw contour lines, at any height, without touching the skull.

Mathematical Society, December 14.—Dr. H. F. Baker, president, in the chair.—J. W. **Nicholson**: The pressure of radiation on a cylindrical obstacle.—H. **Hilton**: Hermitian invariants of a canonical substitution.—E. W. **Hobson**: The fundamental lemma of the calculus of variations and some related theorems.—W. **Burnside**: The outer isomorphisms of a group.—E. B. **Stouffer**: Invariants of linear differential equations.—J. C. **Fields**: A method of proving certain theorems relating to adjointness.

CAMBRIDGE.

Philosophical Society, November 27.—F. A. **Potts**: A new type of parasitism in the Polychæta. A new genus of the polychæt worms, here named Parasitosyllis, was found by Mr. Cyril Crossland at Zanzibar in 1902 as an ectoparasite on other polychæts and nemertines. Attachment is effected by the permanently protracted pharynx, lined by very thick chitinous layers which penetrate widely into the host, becoming quite inseparable from its tissues. The lumen of the pharynx is very restricted, probably only allowing the passage of fluids, absorbed by the pumping action of the proventriculus.—C. **Shearer**, H. M. **Fuchs**, L. **Doncaster**, and J. **Gray**: The experimental hybridisation of echinoids. (1) General account of the experiments (C. **Shearer**). (2) The chemical control of inheritance in echinoid hybrids (H. M. **Fuchs**). The authors described the results of experiments on the hybridisation of echinoids conducted at Plymouth. From a study of the characters of the late larva, which are much more definite than the early characters used by previous investigators, they showed that the inheritance of the parental characters in the hybrids was strictly maternal. (3) Cytological observations of hybrid echinoid eggs (L. **Doncaster** and J. **Gray**). Cross-fertilised eggs, *Echinus acutus* × *E. esculentus*, *E. esculentus* × *E. acutus*, and *E. acutus* × *E. miliaris*, were examined in the early segmentation stages to discover whether omission of chromosomes such as has been described by Baltzer occurs in these crosses. In *E. esculentus* × *E. acutus* the mitotic figures were quite normal. In the converse cross a varying number of chromosomes swell up and develop vesicles in the late prophase stages. These vesicles may be thrown off or remain attached to the chromosome; when thrown off they are frequently left on the outside of the spindle, and not included in the daughter nuclei. Some at least of the chromosomes which have produced vesicles may subsequently divide and behave normally. In *E. acutus* eggs fertilised by *E. miliaris* a similar but less regular and conspicuous formation of vesicles takes place.—Miss A. **Homer**: Note on the condensation of tryptophane with certain aldehydes. Crystalline derivatives of tryptophane have been prepared by the interaction of its aqueous solution with (*a*) formaldehyde, (*b*) glyoxylic acid, and (*c*) glyoxal. Another derivative has been isolated as the result of (*d*) the local heating of a layer of ether resting on the surface of an aqueous solution of tryptophane. There is an interesting relationship between the substances formed in the reactions (*a*), (*b*), and (*d*). Hydrolysis of the formaldehyde derivative and the action of heat on the glyoxylic derivative result, in each case, in the formation of the compound isolated in the reaction (*d*). The investigation of the properties of these substances has shown that in the Adamkiewicz, or glyoxylic, reaction the substance essential to the production of the violet colour is formaldehyde.

PARIS.

Academy of Sciences, December 4.—M. Armand Gautier in the chair.—H. **Poincaré**: The theory of the *quanta*. A study of the hypothesis deduced by Planck from his study of the law of radiation of black bodies. According to this theory, the elements to which the radiation of incandescent solid bodies would be due could only acquire or lose their energy by abrupt steps. This theory could not be expressed by differential equations; and the author has attempted to obtain the Planck law by other hypotheses with this limitation removed, but with negative results.—L. **Lecornu**: The balancing of motors. The problem of balancing motors arranged as in aëroplanes is more difficult than balancing a motor with parallel cylinders. It is shown that the desired result can be theoretically obtained by the addition of two or three auxiliary masses, fixed to suitable points.—A. **Laveran**: Concerning *Trypanosoma rhodesiense*. A study of the trypanosome discovered in Rhodesia by Stephens and Fantham. From the facts described, particularly the observations which demonstrate that an animal having acquired immunity for *T. gambiense* is infected like a new animal by *T. rhodesiense*, that the last trypanosome cannot be identified with *T. gambiense*. Experiments are in progress having for their object a similar comparison of *T. rhodesiense* with *T. brucei*.—A. **Müntz** and E. **Lainé**: The proportion of carbon dioxide in the air of the Antarctic regions. Samples collected between latitudes 64° and 70° show a mean content of 2·05 parts of carbon dioxide per 10,000, the lowest proportions occurring in the highest latitudes. These researches, and those obtained some time ago in latitude 55°, in the neighbourhood of Cape Horn, afford a striking confirmation of the views of Th. Schlœsing on the exchanges of carbon dioxide between sea water and air.—M. **Lannelongue**: Excavations at the hamlet of Séviac, near Montréal (Gers). Discovery of a big toe in bronze. The excavations have disclosed some mosaics in a good state of preservation. Details are given of a bronze toe which was found on the soil, and is remarkable for its vigour and anatomical exactness. It is surmised that it may be an *ex-voto* annexed to a statue in stone or marble, or it may be a fragment of an important bronze statue.—M. Moureu was elected a member of the section of chemistry in the place of the late M. Troost.—MM. **Schaumasse** and **Javelle**: A new comet discovered by M. Schaumasse at the Observatory of Nice, and observed by MM. Schaumasse and Javelle. This comet was found on November 30 with the bent 40-cm. equatorial, and appears as a circular nebulosity 3′ to 3·5′ diameter, with a badly defined nucleus of about the twelfth magnitude. The apparent positions are given for November 30 and December 1.—E. M. **Antoniadi**: Observations of the planet Jupiter in 1911 with the 83-cm. equatorial of the Observatory of Meudon. A detailed description of the planet is accompanied with five illustrations of points of interest.—H. **Deslandres**: Remarks on the preceding communication and on the utility of the observation of the

planets. The similarity between the disturbances in the atmosphere of Jupiter and the sun is pointed out, and also the importance of extending these observations to other planets.—M. **Tzitzéica**: The R networks.—Maurice **Potron**: Some properties of the linear substitutions with coefficients $\geqq 0$ and their application to the problems of production and wages.—Louis **Roy**: Viscosity in the movement of flexible membranes.—M. **Girousse**: The protection of installations with weak currents against disturbances due to alternating currents. Supplementary to an earlier note on the same subject. The limits between which the electromotive force and frequency of the disturbing current may be varied have been worked out.—A. **Guillet**: The measurements of small displacements by electrical means. The electrical method proposed is based on the mutual induction of two circuits, and is of the same order of delicacy as the micrometer screw or the optical interference method.—H. **Pécheux**: The resistance and thermoelectricity of tantalum. From the examination of three wires of different purity, the conclusion is drawn that the specific resistance and thermoelectric power of the tantalum increased with the purity.—P. **Vaillant**: The variations in the conductivity of a phosphorescent body under the action of light.—J. **Carvallo**: The conductivity of pure ether. By careful purification of the ether and the glass apparatus, the electrical conductivity was reduced to less than one-tenth that found by Schröder. Even this figure is regarded by the author as too high, and he considers that it is impossible to study completely the conductivity of pure ether in glass vessels.—Georges **Meslin**: The use of doubly refracting prisms for obtaining interference fringes.—A. **Lafay**: The phenomenon of Magnus. A study of the effect produced by a current of air directed normally against a cylinder rotating with a very high velocity.—André **Brochet**: Plotting the lines of equal potential in an electrolyser.—Eugène **Fouard**: The mechanism of osmosis. The experiments described are not in accord with the usual interpretation of the isotonic coefficients of de Vries, nor with the views of Girard and Henri.—G. **Urbain** and F. **Bourion**: Europous chloride. Europic chloride, $EuCl_3$, was first prepared in a pure state; this, reduced in a current of hydrogen at a temperature between 400° C. and 450° C., gives the lower chloride $EuCl_2$, the properties of which are described.—P. **Gaubert**: The indices of refraction of mixed liquid crystals.—J. **Tournois**: The formation of embryos in the hop by the action of the pollen of hemp. It has been found that the oosphere of the hop commences to segment under the action of hemp pollen. This development only appears under favourable conditions of nutrition, and even under the best conditions the development is always limited. —Ch. **Gravier**: Sexual dimorphism in the Capitellians.—A. **Vaissière**: The Opisthobranchs and the marseniads of the Gulf of Tadjoutah.—Ed. **Chevreux**: The amphipods of the French Antarctic expeditions.—Mieczyslaw **Oxner**: The biological analysis of a series of experiments concerning the attainment of sexual maturity, regeneration, and inanition in *Lineus ruber* and *L. lacteus*.—R. **Goupil**: Researches on *Amylomyces Rouxii*.—Mlle. **Robert**: The influence of calcium on the development and mineral composition of *Aspergillus niger*. Within the limits of accuracy employed (0·05 mg. calcium) calcium does not appear to have any influence on the development of this mould.—M. **Javillier** and B. **Sauton**: Is iron indispensable to the formation of the conidia of *Aspergillus niger*?—Raphael **Dubois**: Atmolysis.—Léon **Pervinquière**: The geology of the extreme south of Tunis, especially in the neighbourhood of Ghadamès.—Emile **Haug**: The geology of Meounes and Garéoult (Var).—L. **Cayeux**: A comparison between the Huronian iron minerals of the United States and the oolitic iron minerals of France.—J. **Thoulet**: A bathylithological map of the coast of the Gulf of Lyons between Saintes-Maries and Palavas and Cape Creus.—E. **Rothé**: The earthquake of November 16.

December 11.—M. Armand Gautier in the chair.—Ph. **van Tieghem**: Lepidariaceæ, a new family of Inovuleæ. —P. **Villard** and H. **Abraham**: The measurement of explosive potentials between 20,000 and 300,000 volts. Between electrodes formed of planes of very large area, above 30,000 volts, the explosive potential is a linear function of the distance of the electrodes. A similar relation has also been shown to hold for the case of spherical electrodes carried to symmetrical potentials.—Paul **Sabatier** and A. **Mailhe**: The preparation of the alcoholic amines by catalysis. An extension of the general method described in an earlier paper, the catalytic action of thoria upon a mixture of the vapours of the alcohol and ammonia. Isopropyl alcohol gives isopropylamine, with a little di-isopropylamine, and diphenylcarbinol gives aminodiphenylmethane. Numerous amines have been prepared, starting with cyclohexanol and its homologues. A modification of the catalytic process is described in which the ammonia is replaced by a primary amine; good yields of mixed secondary amines are obtained.—F. **Quenisset**: Photographs of the planet Venus obtained at the Observatory of Juvisy. The photographs demonstrate for the first time the existence of spots on the surface of this planet.—Kyrille **Popoff**: A cause which may have an influence on the estimation of the magnitude of stars. It is suggested that the luminosity of that part of the sky in which a star is situated may be a cause of the discrepancy between the visual and photographic determination of magnitude.—Henri **Renan**: Results of the discussion of observations made by MM. Lancelin and Tsatsopoulos for determining by wireless telegraphy the difference of longitude between Paris and Bizerta. The usual method has been modified by the introduction of an automatic recording instrument for the method of passages. The personal equation is greatly reduced, as is shown in a set of observations given. —A. **Soret**: A bilateral magnetic audiphone.—G. **Reboul**: Photographic impressions on copper. A plate of polished copper, after coating with a very thin layer of chloride or bromide by exposure to the vapours of chlorine or bromine, will give a positive after exposure to sunlight under a negative. The image is not permanent, even in the dark. —Jacques **Duclaux**: The absorption of gases by porous bodies.—Daniel **Berthelot** and Henry **Gaudechon**: The stability of various types of smokeless powder towards the ultra-violet rays. It is shown that the ultra-violet rays from a quartz mercury vapour lamp accelerates the spontaneous decomposition of smokeless powders. This promises to be a valuable method of investigating the stability of smokeless powders, supplementing the tests at present in use.—A. **Recoura**: A combination of ferric sulphate and alcohol. Contribution to the constitution of ferric sulphate.—Marcel **Guichard**: The formation and decomposition of anhydrous bodies: the case of iodic anhydride.—A. **Béhal** and A. **Detœuf**: The action of monochlorurea upon ketones. Monochlorurea in aqueous solution gives with ketones good yields of the monochlorketones. The preparation of several of these is described, and also of the corresponding semicarbazones.—P. L. **Viguier**: Some derivatives of tetrolic aldehyde and its acetal.—G. **André**: The soluble substances occurring in the plasma of tubercles of the potato. The pieces of potato were immersed in ether, and the aqueous solution thus expelled collected and analysed for nitrogen, phosphoric acid, and potash.—Leclerc **du Sablon**: The transpiration of cactus plants: the influence of light.—MM. **Desgrez**, P. **Regnier**, and R. **Moog**: The influence of trimethylamine chlorohydrate on the nutritive exchanges. In experiments on guinea-pigs and rabbits trimethylamine chlorohydrate caused a reduction in the nitrogenous secretions and an increase in the destruction of ternary compounds.—C. **Gessard**: The action of salts on the coagulation of the blood. A study of the relations between the diastase and calcium salts.—Lucien **Vallery**: Study of the coagulation of albumin by heat. Consequences from the point of view of the estimation of albumin in the urine. The whole of the albumin is not precipitated by heating either in presence of acids or electrolytes. Higher results are obtained by using Tanret's reagent, and reasons are given for the view that these higher figures are correct.—A. **Marie** and A. **Thooris**: Variations of the xipho-costal angle according to attitudes and human types.—Etienne **Rabaud**: Paracephalian and acephalian monsters.—R. **Anthony** and A. S. **de Santa-Maria**: The evolution of the *gyrus reuniens* in the Primates.—A. **Rochaix** and G. **Colin**: The action of the rays emitted by the quartz mercury vapour lamp upon the colorability of the acid-resisting bacilli. Under the action of these rays the acid-

resisting bacilli in the dry state lose their power of taking stains by the processes of Gram, Much, and Ziehl, but the process is not the same for all, since coloration by Much's method persists after the bacilli cease to stain by the other two methods.—V. **Commont**: Chronology of the protohistoric, Neolithic, and Palæolithic industries, and the stratigraphy of the Holocene and Pleistocene deposits in the north of France.—Attale **Riche**: The lacunæ affecting the lower part of the secondary layers at Crussol (Ardèche) and at the eastern edge of the Central Plateau.

THE SYNTHETIC COLOURING MATTERS.

The Chemistry of the Coal-tar Dyes. By Prof. I. W. Fay. Pp. vi+467. (London: Constable and Co., Ltd., 1911.) Price 16*s*. net.

THE rate of progress in the dyestuff industry is admittedly far more rapid than in any other branch of applied chemistry, and the advances made during the past ten or fifteen years have effected an enormous change in the whole aspect of the subject. Very many dyestuffs of former importance have been abandoned or partially replaced, and hundreds of new dyestuffs have been introduced into commerce. New manufacturing processes have superseded older ones, and considerable improvements have been made in the methods of dyeing and printing. The majority of these advances have been directed towards securing a greater degree of fastness to washing, light, and other agencies. Thus in cotton dyeing the want of fastness of the earlier "substantive" or "salt" dyestuffs soon led to attempts to fix these colours after dyeing, by various methods, such as by diazotisation and combination with phenols, by coupling with diazo-compounds, by treatment with formaldehyde, or by fixation with salts of copper or chromium. The introduction in 1894 of Vidal black, and the enormous extension of the group of "sulphide" dyestuffs which shortly followed, provided the cotton dyer with a class of cheap colouring matters of much greater fastness than those of the "salt" class, which they therefore largely replaced. Again, more recently the newly introduced "vat" dyes of the anthracene and indigoid classes, though at present expensive and difficult to apply, bid fair eventually to supplant the "sulphide" dyestuffs for those purposes, in which the highest degree of fastness is of paramount importance, since many members of this class exhibit a resistance to light and washing surpassing that of any of the older organic dyestuffs. On the theoretical side also considerable progress must be recorded. The constitution of many dyestuffs and dyestuff groups has been elucidated, the mechanism of reactions has been rendered clearer, and our views as to the connection of chemical structure with colour and dyeing properties have been extended.

In the presence of such rapid advances, existing text-books soon become out of date, and in presenting a new work it should be the first aim of the author to render an account of the subject from the most modern point of view. This unfortunately has scarcely been accomplished in the work under review. The author has apparently drawn his material chiefly from the standard text-books, to which indeed he gives full acknowledgment. Original sources, such as the scientific and technical journals or the patent literature, do not seem to have been consulted to any considerable extent. In consequence many important dyestuffs and even entire groups of dyestuffs escape mention, whilst undue space is devoted to the description of others that are now obsolete, and for which a short historical reference would have sufficed. Thus, among the azo-dyestuffs we find no account of those derived from pyrazolone, comprising the light-resisting dyes—tartrazine, fast light yellow, &c.; nor of the more recent chrome-azo colours obtained from orthoamidophenols and orthoamidonaphthols; nor of the valuable class of substantive dyestuffs derived from the 2 : 5 : 7-amidonaphtholsulphonic acid. The very important group of anthracene vat dyestuffs, of which indanthrene blue is the typical representative, is also not mentioned; whilst thioindigo red and thioindigo scarlet are the only vat dyestuffs of the indigoid class which are described.

Even amongst the older dyes we note some curious omissions. Thus no reference is made to the thiazol class, which includes primuline, chloramine yellow, and thioflavine, though this group still retains its importance. Again, the stilbene condensation, by which curcumine yellow and the mikado oranges are produced, is only referred to in connection with the preparation of diamidostilbene disulphonic acid, whilst the reactions for the formation of this substance are represented in a manner now proved by recent investigations to be erroneous. In describing the synthetical methods for the manufacture of indigo, no reference is made to the technically important modification of Heumann's process employed by the Farbwerke Hoechst, which consists in adding sodium amide to the phenylglycine melt. Moreover, the starting point in the Sandmeyer synthesis is not chloral and hydroxylamine but diphenylurea.

In regard to the more theoretical aspects of the subject, we miss any full discussion of the relationship of constitution to colour, beyond the older views of Witt. Paraquinonoid and orthoquinonoid formulæ are frequently used indiscriminately and without explanation. Thus, whilst the paraquinonoid formula is given to Lauth's violet, its tetramethyl derivative, methylene blue, is represented on the same page by an orthoquinonoid structure. Similarly, in the general classification of the dyestuffs only paraquinonoid types are given, whilst in the general text the dyes of the azine, oxazine, and thiazine classes are mostly represented by orthoquinonoid formulæ. The structure assigned to quinoline yellow is the old quinophthalone constitution now abandoned for the indanedione formula. Chrysophenine is a diethylether of brilliant yellow, and does not contain a free hydroxyl group as formerly supposed and here represented. The fastness to alkalis of the dyestuffs of the patent-blue class cannot be due to the suggested intramolecular linkage of the ortho-sulphonic group, since a similar effect is produced by halogen atoms, or even by methyl groups when present in the same position.

Apart from the above defects, which perhaps are more serious from the point of view of the technologist than for the general chemical student, the subject is presented in an interesting and readable form, which should render the volume of utility. The printing of the text and formulæ is unusually clear, and for a work of this kind fairly free from errors.

The dedication of a whole chapter to the "seven food colours" permitted by the United States Government, appears somewhat a waste of space even for American readers.

ARTHUR G. GREEN.

CONSTRUCTIVE BIOLOGY.

Some Neglected Factors in Evolution: an Essay in Constructive Biology. By H. M. Bernard. Edited by Matilda Bernard. Pp. xxi+489. (New York and London: G. P. Putnam's Sons, 1911.) Price 12*s.* 6*d.* net.

MANY who know the late Mr. Bernard's work in other fields—notably on Madreporarian corals, the Apodidæ, the Galeodidæ, and the retina—will be interested in this essay in constructive biology. Mr. Bernard was marked by a resolute independence of thought, and this quality, strengthened by his mathematical and philosophical training, is conspicuous in the book before us, a posthumous work, very carefully edited.

The first part of the volume is an exposition of the protomitomic theory, according to which what are called "cells" are merely form-features of some deeper underlying texture, namely, a fundamental linin-chromatin network. In the retina of vertebrates the author found a continuous network with the nuclei at the nodes. He called this fundamental reticulum in living substance, "the protomitomic network." "The connecting filaments were seen to be continuations of the filaments within the nuclei, so that the latter appeared to be merely special tangles of the filamentous network." In some tissues a large amount of cytoplasmic matter is required for their activities, and this tends to obscure the essential reticular structure; in other tissues the filaments are the most obvious structural elements. According to Mr. Bernard's view, which is expounded in a temperate, scholarly, and ingenious argument, the biological unit—both morphological and physiological—is not the cell, but a node in the reticular linin-chromatin system, a stellate linin-chromatin mass from which filaments radiate. By concentration of chromidia (*i.e.* minute chromatin particles which occur in the nodes of the linin network), rearrangement of filaments, and progressive centripetal differentiation, and the like, the first cells may have arisen. They are like enlarged editions of the chromidial units, capable of a larger "life."

This is not the sort of theory that can be called right or wrong; the question is whether it is useful in the interpretation of cellular structure and function. In a series of chapters the main conception—of a continuous filamentous system with nuclei distributed as centres of functional activity—is cleverly used as a key, not only in regard to structural details of epidermis, nervous system, sense organs, and the like, but also in regard to growth, cell-division, and even heredity. We come at length to the idea that organisms differ from one another in the pattern of their protomitomic networks, which is like the morphological side of Haeckel's idea that organisms differ from one another in the rhythm of their minutest protoplasmic particles or plastidules. It is indeed a fundamental biological conception that an organism is an individualised persistence of a specific activity inseparably associated with a specific structure.

In many of the cells that we are in the habit of looking at we are bound to confess that we cannot see anything of the protomitomic system, and the descriptions given by some of the most expert cytologists are not in favour of the author's view, which is essential to his whole theory, that the filaments of the nuclear network are *continuous* with the network of the cell-body. The suggestion is made that the use of osmic acid is to blame for the modern denial of the unity of the reticulum. Apart from the idea of continuity, it is possible to find in many recent researches some corroboration of the author's emphasis on the extra-nuclear chromatin. We think, for instance, of the modern insistence, due very largely to Richard Hertwig, on the importance of the chromidial (*i.e.* extra-nuclear chromatin) apparatus in the cytoplasm. Or we recall the "plastosomes" of Meves, elementary structures in the cytoplasm, which are regarded as the foundations or primordia of ontogenetic differentiations.

The second part of the book contains the author's theory of evolution. It is very interesting, characteristically fresh and independent, but within the space at our disposal we cannot do more than allude to three of its outstanding features. The first is the idea of a cosmic rhythm, which is akin to a suggestion that Herbert Spencer made, but left undeveloped, that "life on the earth has not progressed uniformly, but in immense undulations." As Mr. Bernard expressed it: "Organic life is seen advancing out of the dim past upon a series of waves"; period succeeds period, each with a higher unit—"each evolutionary period can be described by the same formula, the processes in all cases being essentially the same, although the factors involved become increasingly complex." The first period is that of the chromidial unit, the second that of the cell unit, the third that of the gastræal unit, the fourth that of the annelidan unit, the fifth that of man. One must remember, of course, that even so far back as the Cambrian life had got a long way past the simpler expressions of the annelidan unit.

The second outstanding feature is the author's conviction that the Darwinian theory accounts for detailed adaptation rather than for great advances in *type*, and that the production of new types is describable as a kind of colony-formation. This was the lesson that the author learned from his thirteen years of work on corals. "The physical force of life" has had periodic outbursts of growth leading to the production of homogeneous aggregates, to repeated colony-formation, to "raisings of the level of life," to "altogether new organisation." Many naturalists have pondered over colony-formation, and we are not prepared to accept the statement on p. 299, that "colonies are regarded by them merely as accidental knots in the evolutionary chain, of no value to the chain." We feel sure, for instance, that the veteran zoologist of Jena will heartily agree with the thesis which his esteemed student has developed in chapter xvii., that colony-formation is an essential factor in evolution. What we miss, however, is a recognition of alternating periods of aggregation and integration.

The third distinctive feature in the etiology of this book is the recognition of "a psychic element in life." While "the assumption of a special 'vital force' is a

knot gratuitously tied in the tangled skein of physical and psychical phenomena," and while the author "would deprecate the assumption that the psyche has mixed, in any way, as an integral factor in the machinery of the building processes of the forms of life, or in their daily workings as intricate mechanisms," yet he believes that the psyche has been able to exert an influence on the working by either delaying or hastening it. In this the psyche is like Driesch's "Entelechy," which punctuates the transformations of energy within the body.

THE SENSIBILITY OF THE ALIMENTARY CANAL.

The Goulstonian Lectures on the Sensibility of the Alimentary Canal. Delivered at the Royal College of Physicians on March 14, 16, *and* 21, 1911. By Dr. Arthur F. Hertz. Pp. v+80. (London: Henry Frowde and Hodder and Stoughton, 1911.) Price 5*s*. net.

THE lectureship which was founded by the late Dr. Goulston is annually awarded to one of the newly elected fellows of the Royal College of Physicians, and so forms a channel by means of which a junior member of the medical profession may make what has often proved to be the first of a valuable series of additions to physiological and pathological progress. Dr. Hertz, however, to whom the honour was awarded this year, is already well known to his medical brethren, and has published many papers on various subjects, as well as a book on constipation. It is to him and his colleagues at Guy's Hospital that we owe the work by means of which the X-ray method has been rendered an aid in medical, as it had been previously shown to be in surgical, cases, and during recent months allusions have been made in these columns to the value of such research in elucidating the disorders of the alimentary canal.

In the present volume, in which Dr. Hertz republishes his lectures, he has, however, struck a new note, and deals with the sensations arising from this part of the body.

The martyr to dyspepsia needs no reminding how insistent such sensations may be. The man in perfect health, however, is scarcely cognisant of the existence of his internal organs. In pre-anæsthetic days, surgeons discovered that the majority of the internal structures of the body are insensitive to touch; they can be handled, and even cut or burnt without causing any sensations. Dr. Hertz not only confirms this by his careful experimental and clinical observations, but has further shown that the alimentary canal is, with the exception of the œsophagus and the anal canal, also insensitive to sensations of heat and cold. Contact with alcohol, however, applied to any part gives rise to a subjective sensation of warmth.

But, as already suggested in the mention of the dyspeptic, pain is experienced; this sensation, which is probably the most primitive of the senses, as it is so important for protective purposes in the struggle for existence can be elicited, but its only cause is tension or stretching, which in a milder degree is also the cause of the sensation of fulness. If disease spreads to, or the tension is exerted on, peritoneal structures, the pain may become excruciating. This sensibility varies in different people, and is most marked in those with an irritable nervous system, as in neurasthenia, hypochondriasis, and anæmia. But when visceral pain or discomfort is present, all people are alike in their inability to localise it accurately. It is then that the so-called "referred pains" come to the assistance of the physician. By this one means that areas of skin and subjacent muscle related to the same spinal segments that govern the viscera, are the seat of discomfort, pain, and even of tenderness. This aspect of the subject has been taken up especially by Dr. Henry Head, and it is quite possible to localise an internal disorder by a study of the referred pain. The painful, tender patch may not always be in the immediate vicinity of the affected organ, for in growth the skin area, and the internal viscus which send their messages to the same segment of the spinal cord may become widely separated; for instance, the association of liver trouble and shoulder pain is familiar even to the non-medical reader.

The alimentary canal, though destitute of any true tactile sense, is endowed with certain sensations peculiar to itself, namely, hunger and thirst. These two sensations do not run quite on all fours with each other, and of them Dr. Hertz refers to hunger only. This consists not only in a general sensation of malaise, but a local sense of abdominal emptiness. Dr. Hertz believes that the latter is produced by the motor activity of the stomach and intestines during fasting; and this affects consciousness partly because the action is excessive, and partly because the central nervous system is over-excitable in this condition.

The brochure of which we have attempted this brief and imperfect summary will amply repay careful perusal, and hearty congratulations are due to its author, not only for his accurate and well-devised experimental work and observations, but also for the lucid and interesting way in which he has presented them.

W. D. H.

A NEW PRIMER OF PSYCHOLOGY.

The Essentials of Psychology. By Prof. W. B. Pillsbury. Pp. xi+362. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 5*s*. 6*d*. net.

THE task of writing a good elementary text-book on any science is notoriously arduous, and this is especially the case with so difficult a subject as that of psychology. The ideal writer of such a book would be one whose power of taking a broad and unbiassed view of his subject was guaranteed by a thoroughly sound previous training in mathematics, physiology, and philosophy (metaphysics, logic, ethics, &c.), every one of which sciences is absolutely essential to a competent knowledge of psychology in its full extent at the present day. A writer falling short of this ideal is likely to betray the fact by an unevenness, more or less pronounced, in his treatment of different parts

of the subject. In the case of the present book the unevenness, though not entirely absent, is scarcely apparent. It takes the form of slight inadequacy on the mathematical side, appearing in the brief and not entirely unmisleading account of the measurement of sensation intensities, and more prominently in the long and otherwise excellent chapter on "The Interrelations of Mental Function," where the important method of correlation now in general use for the measurement of these interrelations is not mentioned, and is only referred to indirectly by the quotation, in one sentence, of a research somewhat out of date and certainly not representative.

In other respects, Prof. Pillsbury has written an exceptionally useful and effective book, for which one can safely predict a high degree of popularity among students. The earlier chapters are devoted to a very interesting analysis of the general characteristics of consciousness, such as attention, retention, and association, and the descriptions of perception, memory, reasoning, &c., are all based upon this earlier account, and form the later chapters of the book. The discussions of attention, memory, and imagination, reasoning and work, fatigue and sleep, are exceptionally good, and sum up concisely a great many of the results of modern experimental work on these topics. Perception is not so well done. It is surely incorrect to say that "perceptions always involve centrally aroused sensations or memories, as well as sensations" (p. 157). Evidence from pathology and animal psychology makes dead against this view. Inherited structure of the nervous system, as Prof. Stout suggests, "explains" the function better in such cases, and even in normal human psychology these additional mental images and ideas are largely mythical and unidentifiable by introspection.

Another small point: in the chapter on cutaneous sensations no mention is made of the distinctness of sensations of warmth, coolness, and light touch from those of heat, cold, and heavy touch respectively, although this result, based upon the work of Drs. Head, Rivers, and Sherren, is now three years old and well authenticated. A reference to it would not have conflicted with the elementary character of the book. This is one instance among several of the tendency to ignore important work done by English psychologists, which is more pronounced than it might be in some American and Continental writers.

At the end of each chapter of the book there is a series of "exercises" in experimental introspection, for which one is grateful. They add considerably to its value for class-work. W. B.

NUMBER AND QUANTITY.

Grandeurs et Nombres—Arithmétique Générale. By Prof. E. Dumont. Définitions et Propriétés fondamentales des Grandeurs géométriques et de leurs Mesures; Nombres Naturels, Qualifiés, Complexes, Ternions et Quaternions. Pp. xvii+275. (Paris: A. Hermann et Fils, 1911.) Price 10 francs.

IN mathematics, as in other affairs, a great movement happens now and then which is a kind of revolution; and whenever this occurs there is sure to be a body of stalwart veterans, who refuse to budge from their old position, however untenable or worthless it may be.

M. Dumont's book is an illustration of this familiar fact. So far is he from accepting the modern view of mathematical science that it stirs him to a passionate revolt; he invokes the shades of the old masters, from Archimedes down to Hamilton, and denounces the logicians as conspiring to make mathematics a barren pastime, instead of the instrument of the natural philosopher.

In order to justify his protest, he has attempted to give a theory based on the definition of a number as the ratio of two quantities. As might be expected, he constantly begs the question, and makes a variety of tacit assumptions, far more complicated than those really necessary in applying mathematics to physical phenomena. For instance, he says (p. 7), "To multiply a quantity G by the number A_1/A is to apply to G the same treatment which, applied to A, produces A_1." What is "the same treatment"? G may be a length, and A, A_1 volumes or masses; how can "the same treatment" be defined without begging the whole question at issue? A little further on we read that "it is not always possible to multiply a quantity (*grandeur*) by a number, as we shall see in the theory of quaternions." Here our Don Quixote betrays some sense of discomfort in his antiquated armour; the reason appears subsequently. Length is defined (p. 114) as "une grandeur linéaire relative et orientée . . . qui se développe dans deux sens opposés, à partir d'une origine arbitraire, et dans une direction variable." On p. 195 we read, "the ratio of two vectors or of two angles, thus conceived, is called a quaternion or quaternary number"; after this it is not surprising to find a treatment of quaternions quite needlessly complex, with definitions stated as theorems, and formulæ of the most repellent kind; moreover, we have a separate chapter on "ternions," which are only special cases of quaternions. To make confusion worse confounded, the author writes (a, b denoting vectors) a/b as the equivalent of $b^{-1}a$, and calls it "the ratio of a and b," while $a:b$ is the equivalent of ab^{-1}, and is called "the quotient of a by b." Almost immediately before this we read: "Quant à a/b, on écrira aussi volontiers $a/b=b^{-1}a$ que $a/b=ab^{-1}$"!

M. Dumont expressly denounces the views of his distinguished countrymen Jules Tannery and M. Hadamard; they need no better justification than is unconsciously given by this attempt to prove them wrong. At the same time, some of us will partly sympathise with M. Dumont, although entirely disagreeing with his doctrine. It would indeed be lamentable if mathematics were to be entirely divorced from its physical applications, and simply cultivated as an intellectual game. Fortunately, there is no reason to fear that this will ever be the case; electrical theory alone will continue to attract many of the ablest mathematicians of the time. And however fully we may admit that arithmetical analysis is independent of measurement, we cannot ignore the fact that measurements must precede any physical theory of a mathematical kind. Moreover, the data properly belonging to any physical science are not themselves

mathematical; the business of the mathematician (as Kirchhoff and Pearson have so well pointed out) is to provide, if possible, a descriptive scheme, such, for instance, as the so-called "law" of gravitation and its mathematical consequences, which reduces a complex group of phenomena to an intelligible system. Anything beyond this is metaphysics, and outside the domain of physical science and mathematics as well.

G. B. M.

APPLICATIONS OF PHOTOGRAPHY IN SCIENCE AND TECHNICS.

Angewandte Photographie in Wissenschaft und Technik. Edited by K. W. Wolf-Czapek. In vier Teilen. Pp. xvi+100+37 plates; pp. 119+41 plates; pp. 95+42 plates; pp. 98+37 plates. (Berlin: Union Deutsche Verlagsgesellschaft Zweigniederlassung Berlin, 1911.) Price 20 marks.

THERE is scarcely a science to-day wherein photography is not employed in one form or another, and even our industries make use of it in a host of different ways. So universal has become the adoption of this form of obtaining permanent records of things living and inanimate that specialists have sprung up in all directions who are able to bring to bear a great amount of experience, not only in how to apply photography to the particular case in question, but the most appropriate apparatus and methods to be adopted to secure the best results.

If, for instance, one wishes to launch out in the domain of photomicrography the first step is to find out what has been written on the subject, and then secure a book which is recommended as containing the best methods to be followed. Or, again, the special field of photographing fast-moving objects, like rifle bullets, is one that requires a good deal of attention before satisfactory results can be obtained. It often happens that one wishes to tackle one branch of photographic work which is outside the domain of that to which one is accustomed, and hence there follows an inquiry into the methods, special apparatus, and material required.

Now the work under review is a veritable *vade mecum* in this respect, for it deals, and deals exceedingly well, with the application of photography in practically every important aspect, both in science and the technics. It is only natural that for such a volume to be of value it must necessarily be the work of numerous men, for no one man can have had experience in all the multitude of applications. Herr K. W. Wolf-Czapek has done well therefore in gathering round him a number of workers who are authorities on the branches about which they write, and the result is one that is eminently satisfactory. The book itself contains 407 pages and 159 plates, with 470 illustrations on them, so that the reader will at once gather the fact that both methods and examples are amply illustrated and described. The contents are divided into four parts under general subheads, namely (1) inorganic physical sciences, such as physics, chemistry, astronomy, &c.; (2) organic physical sciences, such as botany, zoology, &c.; (3) technical science, such as photography applied to war, engineering press, &c.; and lastly (4) social problems, as anthropology, criminal statistics, &c. The list of coworkers is too numerous to be given here, but when it is seen the reader can rest content that the text was in good hands. It is interesting to note that the volume was inspired by the International Photographic Exhibition held in Dresden in 1909, and that Herr Wolf-Czapek took the opportunity to utilise the exhibits as the groundwork for the volume.

In addition to a very carefully prepared table of contents, a subject-index and a name-register, the value of the work is considerably enhanced by the large number of references to the literature of the various subjects treated.
